

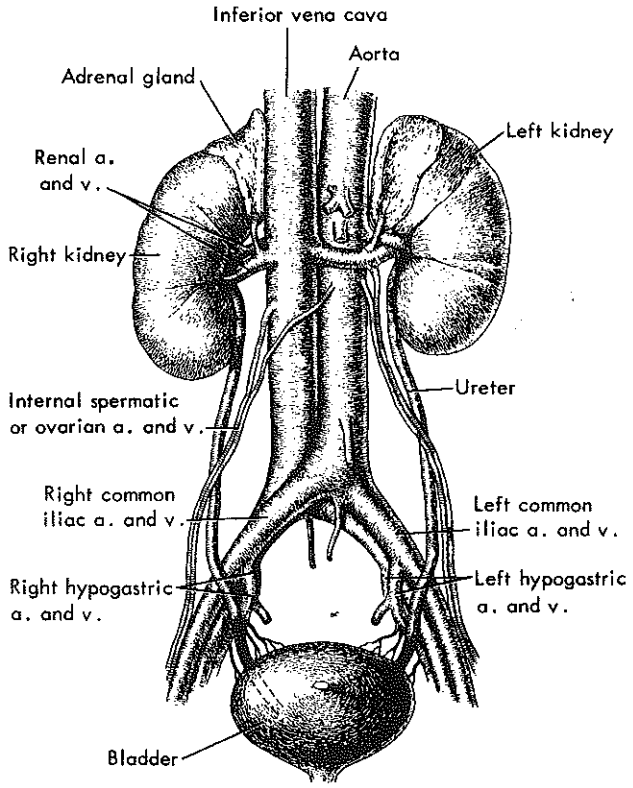

Figure 45-1 The vascular and anatomical relationships of the kidneys in man. *(From Leaf A, Cotran RS. Renal pathophysiology. 3rd ed. Oxford: Oxford University Press, 1985. Reproduced by permission of Oxford University Press.)*

cortex, maintaining the highly active tubular cells.[383] The maintenance of renal blood flow is essential to kidney function, and there is a complex array of intrarenal regulatory mechanisms that ensure that it is maintained across a wide range of systemic blood pressures (see discussion later in this chapter).[383] The renal glomerular perfusion pressure is independent of the systemic pressure between 90 and 200 mm Hg, being maintained at a constant 45 mm Hg. Renal blood flow is now rarely measured in clinical practice. Details of some of the approaches adopted for the measurement of renal blood flow may be found in the 3rd edition of this textbook.

Nephron

The functional unit of the kidney is the *nephron.* Each kidney has been reported to contain between 1 and 1.5 million nephrons, although a 1992 estimate suggests a slightly lower range, with a mean of 600,000 nephrons.[303] The number of nephrons that an individual is born with (the "nephron dose") may determine that individual's susceptibility to renal injury.

The nephron consists of a glomerulus, proximal tubule, loop of Henle, distal tubule, and collecting duct (Figure 45-2). The collecting ducts ultimately combine to develop into the renal calyces, where the urine collects before passing along the ureter and into the bladder. The kidney is divided into several lobes. The outer, darker region of each lobe, the cortex, consists of most of the glomeruli and the proximal and distal tubules. The cortex surrounds a paler inner region, the medulla, which is further divided into a number of conical areas known as the renal pyramids, the apex of which extends toward the renal pelvis, forming papillae. Medullary rays are visible striations in the renal pyramids, which connect the kidney cortex with the medulla. They are composed of descending (straight proximal) and ascending (straight distal) thick limbs of Henle and collecting ducts and associated blood vessels (the vasa recta). The central hilus is where blood vessels, lymphatics, and the renal pelvis (containing the ureter) join the kidney.

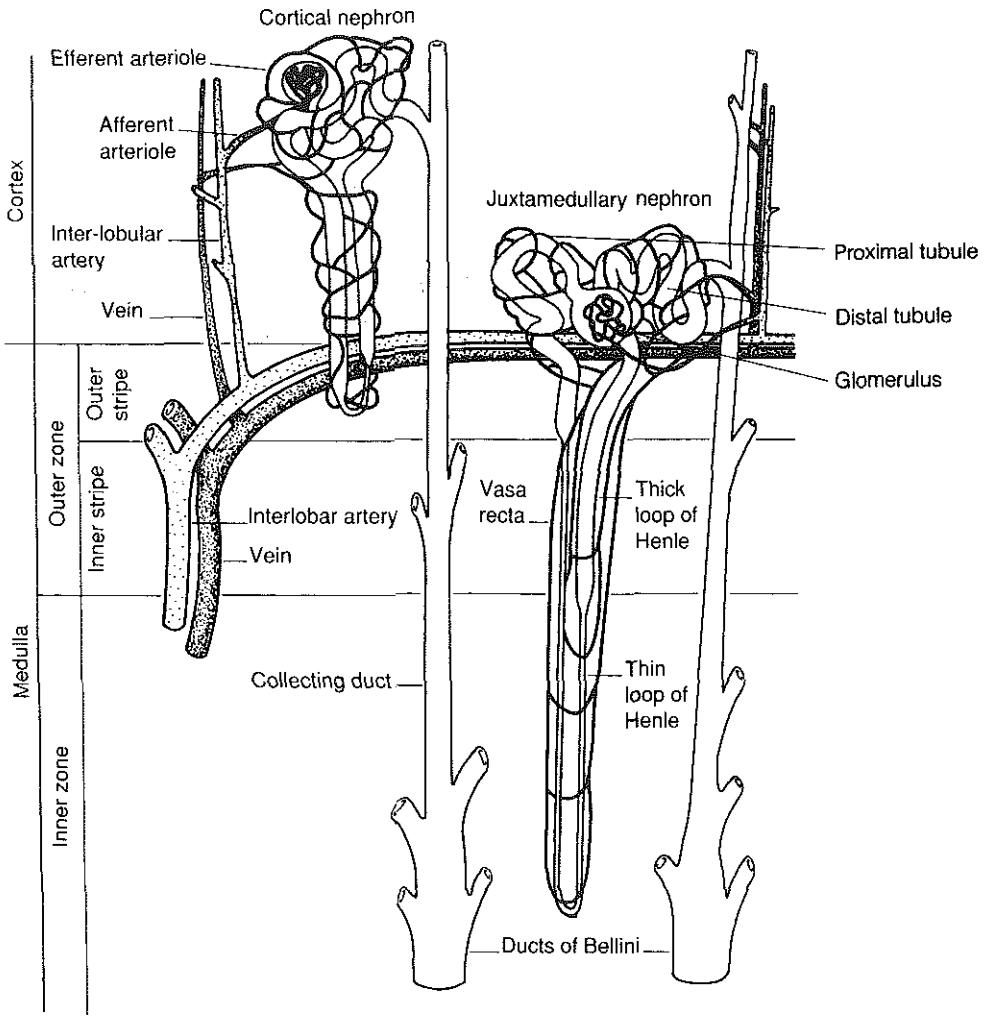
Glomerulus

The glomerulus is formed from a specialized capillary network. Each capillary develops into approximately 40 glomerular loops around 200 μm in size and consisting of a variety of different cell types supported on a specialized basement membrane (Figure 45-3, top). There are endothelial and epithelial cells that act in concert with the specialized glomerular basement membrane to form the glomerular filtration barrier, and then there are mesangial (types I and II) cells. The *capillary endothelial* cells are about 40 nm thick and are in contact with each other, but between these cells there are many circular fenestrations (pores) with diameters of between 40 and 100 nm. The fenestrations are lined with a surface coating of negatively charged glycoprotein about 12 nm thick, but allow virtually free access of plasma to the basement membrane, which forms the only continuous barrier between the capillary blood and glomerular filtrate.

The *basement membrane* (see Figure 45-3, bottom) is approximately 300 nm thick in adult humans and consists of three distinct electron-dense layers: the *lamina rara interna,* the *lamina densa,* and the *lamina rara externa.* The lamina densa consists of a close feltwork of fine, mainly type IV, collagen fibrils (each 3 to 5 nm thick) embedded in a gel-like matrix of glycoproteins and proteoglycans. This forms the main size discriminant barrier to protein passage into the tubular lumen. The other two layers of the basement membrane are rich in negatively charged polyanionic glycoproteins, such as heparin sulfate; these form the main charge discriminant barrier to the passage of proteins.

The *epithelial cells* lining Bowman's capsule (see Figure 45-3, top) are called *podocytes* and have an unusual octopus-like structure in that they have a large number of extensions or foot processes that are embedded in the basement membrane. The foot processes from adjacent podocytes are interdigitated to form filtration slits, which are covered by a loose, highly hydrated anionic mucopolysaccharide gel that is rich in sialic acid. The resulting structure is relatively impermeable to most proteins above 60 kDa, but passage of proteins is also modulated by their charge and shape.

The final cellular components of the glomerulus are the *mesangial cells,* which are found in the central part between



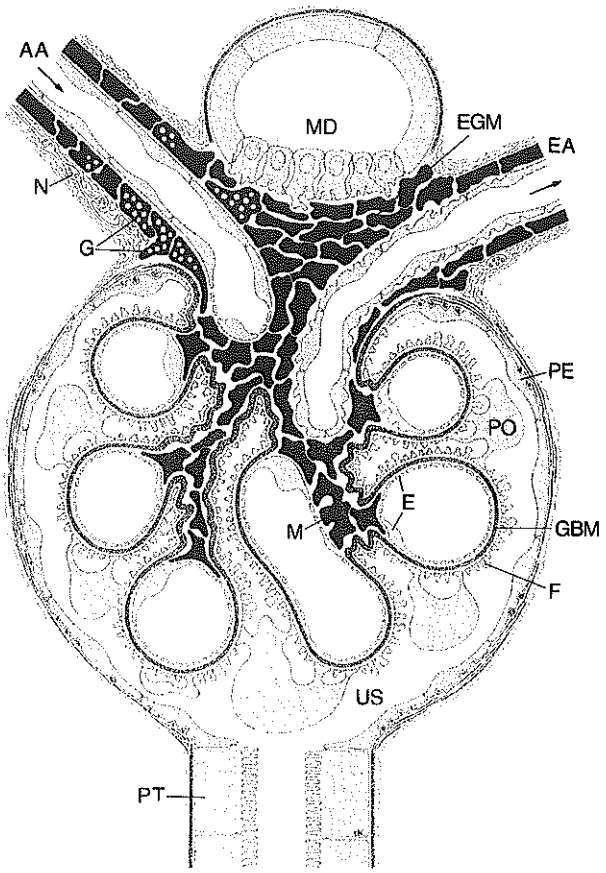


Figure 45-2 Diagrammatic representation of the nephron, the functional unit of the kidney, illustrating the anatomical and vascular arrangements. *(From Pitts RF: Physiology of the kidney and body fluids. 3rd ed. Chicago: Year Book Medical Publishers, 1974:8p.)*

and within the capillary loops suspended in a matrix that they synthesize. These cells are phagocytic and take up circulating antigen-antibody complexes that can provoke glomerulonephritis. These macromolecules are then cleared from the mesangial cells by phagocytosis and other mechanisms, such as movement by way of the glomerular stalk to the juxtaglomerular region and then via the renal lymphatics, or by regurgitation into the glomerular capillary. One view of this role of the mesangium is that it keeps the glomerular filter clear of large macromolecules, because the inner layer of the basement membrane (the lamina rara interna) is continuous with the mesangium. Mesangial cells also have characteristics of smooth muscle cells, because they are rich in myofilaments and can contract in response to a variety of stimuli (e.g., angiotensin II and arginine vasopressin). Contraction of mesangial cells can have a significant effect on the glomerular filtration rate (GFR) by reducing the available filtration surface.

Proximal Tubule

Bowman's capsule forms the beginning of the tightly coiled, proximal convoluted tubule (*pars convoluta*), which on its progress toward the renal medulla becomes straightened and is then called the *pars recta*. The human proximal tubule is about 15 mm long. The epithelial cells lining the convoluted section are cuboidal/columnar cells with a luminal brush border consisting of millions of microvilli, which enormously expand the surface area for absorption of tubular fluid. Ultrastructurally, there are three main segments, S1, S2, and S3, which consist of very different cell types (Figure 45-4). The transition from S1 to S2 is gradual and occurs in the latter part of the convoluted section. The S2 to S3 transition occurs deep within the medullary rays. The different segments are distinguished by different types of brush border, density of mitochondria, and degree of cellular interdigitation. There are also functional differences, as demonstrated by the region-specific nephrotoxicity of

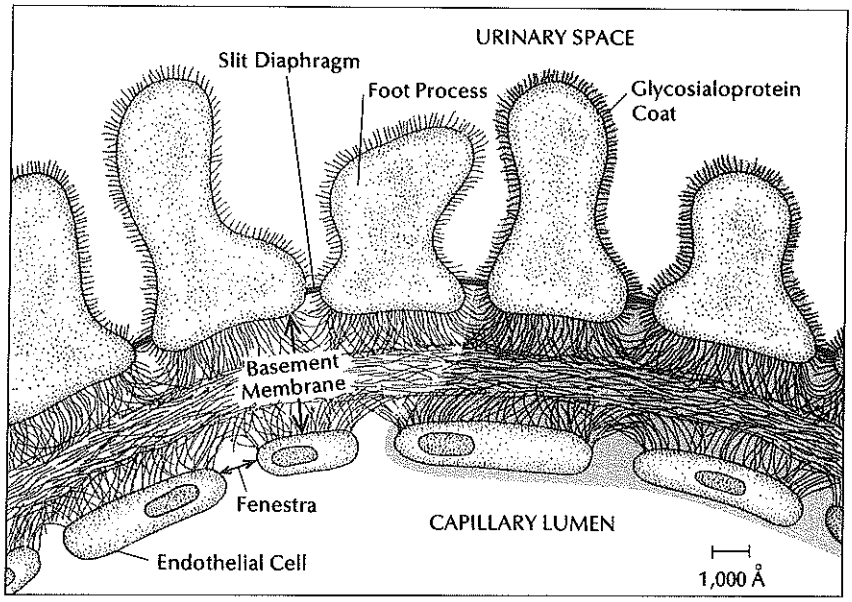

Figure 45-3 The glomerular cells and the glomerular filtration barrier. *Top,* Longitudinal section through a glomerulus and its juxtaglomerular apparatus. The capillary tuft consists of a network of specialized capillaries, which are outlined by a fenestrated endothelium (E). At the vascular pole the afferent arteriole (AA) enters, branching into capillaries immediately after its entrance; the efferent arteriole (EA) is established inside the tuft and passes through the glomerular stalk before leaving at the vascular pole. The capillary network and the mesangium are enclosed in a common compartment bounded by the glomerular basement membrane (GBM). Note that there is no basement membrane at the interface between the capillary endothelium and the mesangium. The glomerular visceral epithelium consists of highly branched podocytes (PO), which, in a typical interdigitating pattern, cover the outer aspect of the GBM. At the vascular pole, the visceral epithelium and the GBM are reflected into the parietal epithelium (PE) of Bowman's capsule, which passes over into the epithelium of the proximal tubule (PT) at the urinary pole. At the vascular pole the glomerular mesangium is continuous with the extraglomerular mesangium (EGM), which consists of extraglomerular mesangial cells and an extraglomerular mesangial matrix. The EGM and the granular cells (G) of the afferent arteriole, along with the macula densa (MD), establish the juxtaglomerular apparatus. All cells that are suggested to be of smooth-muscle origin are shown in black. *US,* Urinary space; *F,* foot processes; *N,* sympathetic nerve terminals; *M,* messenger cells. *(From Elger M, Kriz W. The renal glomerulus—the structural basis of ultrafiltration. In: Cameron JS, Davison AM, Grunfeld JP, Kerr D, Ritz E, eds. Oxford Textbook of Clinical Nephrology (vol. 1). 2nd ed. Oxford: Oxford University Press, 1998: Chapter 3.1. Reproduced by permission of Oxford University Press.) Bottom,* Glomerular capillary wall. In glomerular filtration, filtered fluid is believed to traverse the capillary wall via an extracellular route, that is, through endothelial fenestrae, basement membrane, and slit diaphragms. Circulating polyanions (e.g., albumin) are thought to be retarded by the rich distribution in inner barriers of negatively charged sialylated glycoproteins (*shaded area* in schematic diagram). *(From Brenner BM, Beeuwkes R, III. The kidney in health and disease: III. The renal circulations. Hospital Practice 1978;13:35-46.)*

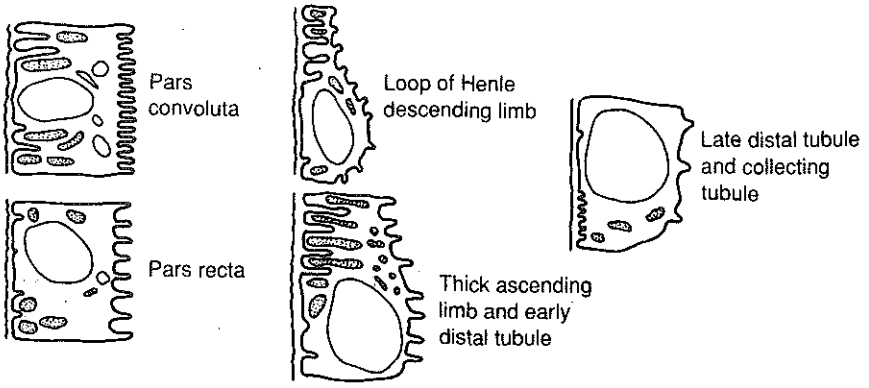

Figure 45-4 Microstructure of the proximal tubule showing the morphology of cells in the various nephron segments. In the diagram, for each cell the tubule is on the right. The cell membrane on this side is the apical, mucosal, or luminal membrane. The cell membrane on the opposite side of the cell, resting on the basement membrane (basal lamina), is the basal, serosal, or peritubular membrane. In the pars convoluta of the proximal tubule, the cells have a dense brush border (microvilli), increasing the luminal membrane surface area by a factor of about 40. Basolaterally, these cells interdigitate with each other extensively. In the pars recta, there are fewer mitochondria (suggesting that the transport functions of these cells are less well developed than those of the pars convoluta cells). The brush border is also less extensive. The cells of the descending limb of the loop of Henle are rather flat and have few interdigitations and sparse microvilli. In the thin ascending limb of the loop of Henle (not illustrated), the cells have a similar flattened appearance, but have dense interdigitations with each other. Generally the transition from the descending type of epithelium to the ascending type occurs just before the bend. The transition from the thin ascending limb to the thick ascending limb occurs abruptly at the junction of the inner and outer zones of the medulla. In most species, there are only minor differences between cells of the thick ascending limb and those of the early distal tubule. The late distal tubule and collecting tubule have a number of cell types, but the transport functions are essentially similar in both of these anatomical segments. *(From Lote CJ. Principles of renal physiology. 4th ed. London: Kluwer Academic Publishers, Chapter 2, 2000.)*

certain drugs or metals (e.g., mercury is an S3-segment–specific toxin).

The proximal tubule is the most metabolically active part of the nephron, facilitating the reabsorption of 60% to 80% of the glomerular filtrate volume—including 70% of the filtered load of sodium and chloride, most of the potassium, glucose, bicarbonate, phosphate, and sulfate—and secreting 90% of the hydrogen ion excreted by the kidney (Table 45-1).

Loop of Henle

The pars recta drains into the descending thin loop of Henle, which after passing through a hairpin loop becomes first the ascending thin limb and then the thick ascending loop. In short-looped nephrons, where there are no ascending thin limbs, the loops of Henle are situated deep in the renal medulla. The cells of the ascending thin limb are very similar to those in the descending (with little brush border, flattened and interdigitated), but there are important differences in their permeability to water and in their capability for active transport. The thick ascending limb is lined with cuboidal/columnar cells similar in size to those in the proximal tubule, but they do not possess a brush border. At the end of the thick ascending limb, near where it reenters the cortex and closely associated with the glomerulus and the efferent arteriole, there is a cluster of cells known as the *macula densa* (Figure 45-5, see discussion later in this chapter). The main role of the loop of Henle is to provide the ability to generate a concentrated urine, hypertonic with respect to plasma and with a capability that has only been demonstrated for mammalian and avian kidneys; there are several other functions (see Table 45-1).

Distal Tubule

The cells forming the distal tubule of the nephron start at the macula densa and extend to the first fusion with other tubules to form the collecting ducts. However, they have been shown to consist of three morphologically and functionally distinct segments. The first two contain similar cell types, with infoldings of the basal lamina surrounding the mitochondria. The third segment contains cells known as principal cells that have smaller infoldings and contain fewer mitochondria. All three segments have Na^+, K^+-ATPase activity. Interspersed between them are the intercalated cells, which have cytoplasmic extensions and high carbonic anhydrase activity but no Na^+, K^+-ATPase activity. Sodium

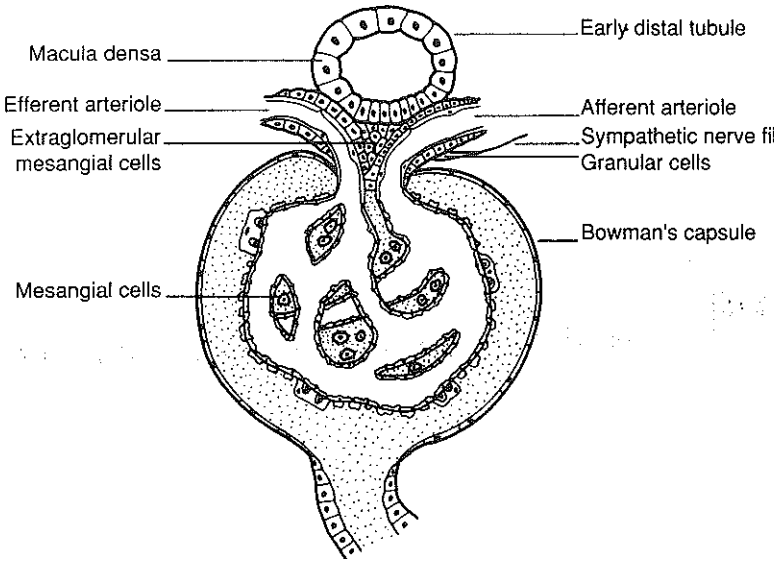

Figure 45-5 The juxtaglomerular apparatus. The beginning of the distal tubule (i.e., where the loop of Henle reenters the cortex) lies very close to the afferent and efferent arterioles, and the cells of both the afferent arteriole and the tubule show specialization. The cells of the afferent arteriole are thickened, granular (juxtaglomerular) cells and are innervated by sympathetic nerve fibers. The mesangial cells are irregularly shaped and contain filaments of contractile proteins. Identical cells are found just outside the glomerulus and are termed extraglomerular mesangial cells or Goormaghtigh cells. *(From Lote CJ. Principles of renal physiology. 4th ed. London: Kluwer Academic Publishers, 2000:Chapter 2.)*

chloride reabsorption occurs in all three; potassium secretion occurs in the first, and hydrogen ion excretion occurs in the latter two.

Collecting Duct

The collecting ducts are functionally part of the nephron, but are embryologically distinct from it and are formed from a number of distal tubules, usually about six. These are successively joined by other tubules to form ducts of Bellini, which ultimately drain into a renal calyx. The cells lining the collecting duct are cuboidal and have a less granular cytoplasm than those of the proximal tubule, although there are a number of interspersed cells with a more granular cytoplasm whose function remains uncertain.

Juxtaglomerular Apparatus

Where the ascending loop of Henle passes very close to the Bowman's capsule of its own nephron, the cells of the tubule and the afferent arteriole show regional specialization (see Figure 45-5). The tubule forms the macula densa and the

arteriolar cells are filled with granules (containing renin) and are innervated with sympathetic nerve fibers. This area is called the juxtaglomerular apparatus (JGA). The JGA plays an important part in maintaining systemic blood pressure through regulation of the circulating intravascular blood volume and sodium concentration. The proteolytic enzyme renin is released primarily in response to decreased afferent arteriolar pressure and decreased intraluminal sodium delivery to the macula densa. Renin release from the macula densa is also influenced by renal cortical prostaglandins (predominantly PGI_2) and the sympathetic nervous system. The released renin then acts on the plasma protein angiotensinogen to generate angiotensin I. This is converted in the lungs by angiotensin converting enzyme (ACE) to the potent vasoconstrictor and stimulator of aldosterone release, angiotensin II (AII). The vasoconstriction and aldosterone release (with increased distal tubular sodium retention) act in concert with the other action of AII, to increase the release of antidiuretic hormone (ADH [vasopressin]) and to increase proximal tubular sodium reabsorption, intravascular volume, and pressure. AII also has an inhibitory effect on renin release as part of a negative feedback loop. Associated with the JGA are extraglomerular mesangial cells known as Goormaghtigh cells; although their function is unclear, they are thought to provide electrical coupling among themselves and to the mesangium and glomerular arterioles.[93]

Renal Interstitium

In a normal renal cortex, the interstitium is sparse (7% to 9% by volume) as the tubules lie very close together; however, a large proportion of the reabsorbed tubular fluid has to traverse a true interstitial space before entering the capillaries. The interstitium contains a variety of cells. The majority (type I) are fibroblasts, and the minority (type II) resemble lymphocytes. Subpopulations of the interstitial fibroblasts have been demonstrated using immunohistochemistry.[344]

The medullary interstitium contains a further specialized cell, the lipid-laden interstitial cells, which are arranged in a characteristic ladderlike pattern across the loops of Henle and capillaries. The extracellular space is rich in glycosaminoglycans, resulting in a gelatinous matrix that contains various poorly characterized osmolytes, osmotically active molecules that help stabilize the high osmotic gradient essential to the countercurrent mechanism involved in the generation of a hyperosmotic urine. The interstitium becomes very important in a variety of kidney diseases—and its expansion, as a consequence of, or cause of, nephron loss—plays an important part in progressive kidney disease. Interstitial expansion includes cellular infiltration and increased interstitial matrix synthesis and interstitial fibrosis.

KIDNEY FUNCTION AND PHYSIOLOGY

The major functions of the kidneys include filtration, reabsorption, and excretion. The kidneys integrate these functions to maintain homeostasis and regulate the internal milieu (Table 45-2).

TABLE 45-2 Important Components of Kidney Function

Filtration	Preparation of an Ultrafiltrate
Reabsorptive	Glucose, amino acids, electrolytes, proteins
Homeostatic	Extracellular volume, acid-base status, blood pressure, electrolytes
Metabolic	Synthetic: glutathione, glyconeogenesis, ammonia Catabolic: hormones, cytokines
Endocrine	Erythropoietin synthesis, activation of vitamin D

Excretory and Reabsorptive Functions

The *excretory function* of the kidneys serves to rid the body of many end products of metabolism and any excess of inorganic substances ingested in the diet. Waste products include the nonprotein nitrogenous compounds urea, creatinine, and uric acid; a number of other organic acids, including amino acids, are excreted in small quantities. Dietary intake contains a variable and usually excessive supply of sodium, potassium, chloride, calcium, phosphate, magnesium, sulfate, and bicarbonate. The efficiency of the homeostatic role in kidney function is illustrated by the way the sodium content of the body is maintained essentially constant, regardless of whether daily sodium intake is 1 or 150 mmol or more. Daily intake of water is also variable and may, on occasion, greatly exceed the minimal requirements of the body. Under such circumstances, water becomes additional waste material requiring excretion. To achieve excretion of the metabolic wastes and the ingested surpluses without disrupting homeostasis, the kidneys must exercise both their *excretory* and *reabsorptive* functions.

Mechanisms for the regulation of electrolytes, nitrogenous wastes, and organic acids are similar although not identical. For all except potassium and hydrogen ions and a few organic acids, the maximal excretory rate is limited or established by their plasma concentrations and the rate of their filtration through the glomeruli. Bulk transfer of substances from blood to glomerular filtrate determines the initial mass on which the nephron must operate to produce and excrete urine. Thus the maximal amount of substance excreted in urine does not exceed the amount transferred through the glomeruli by ultrafiltration except in the case of those substances capable of being secreted by tubular cells. Depending on the activity of the renal tubular epithelial cells and their several reabsorptive capacities, excreted amounts of urinary constituents are in general less than the amounts filtered. Because of this general behavior, for many substances a general estimate of the excretory capacity of the kidneys

can be obtained by measuring either the glomerular filtration rate (GFR) or some variable that is closely related to it. The primary objective in evaluating renal excretory function is to detect quantitatively the degradation of normal capacities or the improvement of impaired ones.

Definitions

Urine is defined as a fluid excreted by the kidneys, passed through the ureters, stored in the bladder, and discharged through the urethra.[93] In health, it is sterile and clear, and has an amber color, a slightly acid pH, and a characteristic odor. In addition to dissolved compounds it contains a number of cellular fragments, complete cells, proteinaceous casts, and crystals (formed elements). Changes in these formed elements are studied using urine microscopy. Urine from a healthy individual should be clear, with a pH of about 5.0 to 6.0 and a specific gravity of about 1.024 g/mL. There is a normal turnover in tubular cells, and these are shed into the urine.

Urination, also termed *micturition,* is the discharge of urine. In normal adults adequate homeostasis is maintained with a urine output of about 500 mL/day. Alterations in urinary output are described as *anuria* (<100 mL/day), *oliguria* (<400 mL/day), or *polyuria* (>3 L/day or 50 mL/kg body weight/day).[323] The most common disorder of micturition is altered frequency, which may be associated with increased urinary volume or with partial urinary tract obstruction (e.g., in prostatic hypertrophy).

Formation of Urine—An Overview

The first step in urine formation is filtration of plasma water at the glomeruli. A net filtration pressure of about 17 mm Hg in the capillary bed of the tuft drives the filtrate through the glomerular membrane. The filtrate is called an *ultrafiltrate* because its composition is essentially the same as that of plasma, but with a notable reduction in molecules of molecular weight exceeding 15 kDa. Each nephron produces about 100 μL of ultrafiltrate per day. Overall, approximately 170 to 200 L of ultrafiltrate pass through the glomeruli in 24 hours. In the passage of ultrafiltrate through the tubules, reabsorption of solutes and water in various regions of the tubules reduces the total urine volume, which typically ranges between 0.4 and 2 L/day.

Transport of solutes and water occurs both across and between the epithelial cells that line the renal tubules. Transport is both active (energy requiring) and passive, but many of the so-called passive transport processes are dependent upon or secondary to active transport processes, particularly those involving sodium transport. All known transport processes involve receptor or mediator molecules, many of which have now been identified and characterized using molecular biological techniques. The activity of many of these molecules is regulated by phosphorylation facilitated by protein kinase C or A.[164,290] Their renal distribution has been shown to correlate with the known regional functional activities, but the same transporters, or isoforms of them,

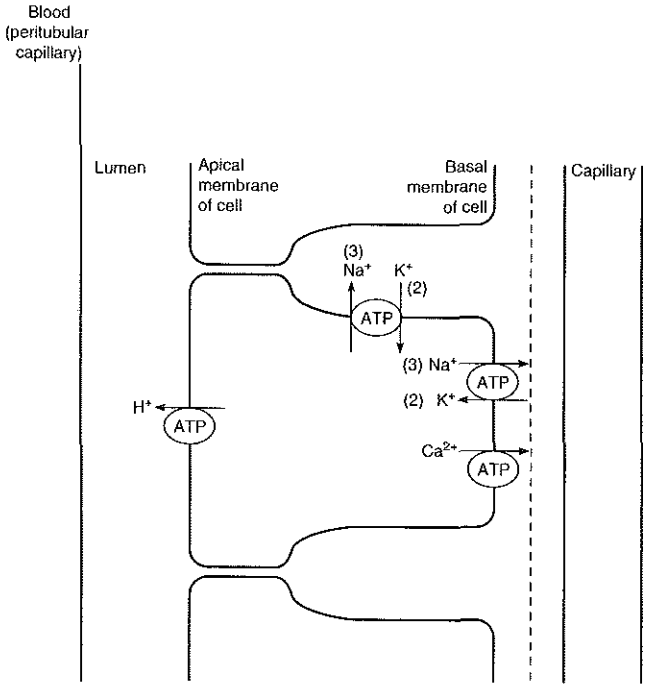

Figure 45-6 Tubular reabsorptive mechanisms: the major primary active transport processes in the proximal nephron. The renal tubular epithelium consists of a single layer of cells. At the luminal side, adjacent cells are in contact (the tight junction), whereas toward the basal side of the cells, there are gaps between adjacent cells (lateral intercellular spaces). *(From Lote CJ. Principles of renal physiology. 4th ed. London: Kluwer Academic Publishers, 2000:Chapter 4.)*

can be found in other tissues, particularly the digestive tract. There are, for instance, at least five independent proximal tubular transport processes for amino acids, including those for (1) basic amino acids plus cystine, (2) glutamic and aspartic acid, (3) neutral amino acids, (4) imino amino acids, and (5) glycine.[470] There are inherited disorders of tubular transporters, discussed later in this chapter, and a well-known generalized disorder affecting all of the transport processes, causing Fanconi syndrome.

Direct coupling of adenosine triphosphate (ATP) hydrolysis is an example of an active transport process. The most important of these in the nephron is Na^+, K^+-ATPase, which is located on the basolateral membranes of the tubuloepithelial cells (Figure 45-6). This enzymatic transporter accounts for much of renal oxygen consumption and drives more than 99% of renal sodium reabsorption. Other examples of primary active transport mechanisms are a Ca^{2+}-ATPase, an H^+-ATPase, and an H^+, K^+-ATPase. These enzymes establish ionic gradients, polarizing cell membranes and thus driving secondary transport processes.

Renal epithelial cell membranes also contain proteins that act as ion channels. For example, there is one for sodium that is closed by amiloride and modulated by hormones such as atrial natriuretic peptide (ANP). Ion channels enable much

faster rates of transport than ATPases but are relatively fewer in number, approximately 100 sodium and chloride channels as against 10^7 Na^+, K^+-ATPase molecules per cell.

In the tubules, the solute composition of the ultrafiltrate is altered by the processes of reabsorption and secretion, so that the urine excreted may have a very different composition from that of the original filtrate. Different regions of the tubule have been shown to specialize in certain functions. In the proximal tubule, 60% to 80% of the ultrafiltrate is reabsorbed in an obligatory fashion, along with sodium, chloride, bicarbonate, calcium, phosphate, sulfate, and other ions. Glucose, a threshold substance,* is virtually completely reabsorbed, predominantly in the proximal tubule by a passive but sodium-dependent process that is saturated at a blood glucose concentration of about 10 mmol/L. Uric acid is also reabsorbed in the proximal tubule by a passive sodium-dependent mechanism, but there is also an active secretory mechanism. Creatinine is also secreted but only to a small extent, approximately 0.14 mmol/min. There is a well-characterized group of proton-coupled peptide transporters, some of which also transport β-lactam antibiotics, ACE inhibitors, and some of the statin group of drugs.[470]

Certain nonbiological compounds, such as phenolsulfonphthalein (PSP) and *p*-aminohippurate (PAH) are secreted by the proximal tubule and have been used for the evaluation of renal tubular secretory capacity. When blood levels of creatinine increase above normal, creatinine is secreted in this region of the nephron. In the loops of Henle, chloride and more sodium without water are reabsorbed, generating dilute urine. Water reabsorption in the more distal tubules and collecting ducts is then regulated by ADH. In the distal tubule, secretion is the prominent activity; organic ions, potassium ions, and hydrogen ions are transported from the blood in the efferent arteriole into the tubular fluid. It is also this region that secretes hydrogen ions and reabsorbs sodium and bicarbonate to aid in acid-base regulation. Paracellular (between cell) movement is driven predominantly by concentration, osmotic, or electrical gradients.

Other secretory products of the nephron are not well understood. For example, a significant proportion of normal urinary protein is formed by Tamm Horsfall glycoprotein (THG). This protein is secreted by the distal tubule and is thought to play a role in inhibiting kidney stone formation, but this has not been confirmed conclusively. The tubular epithelial cells also synthesize a vast range of growth factors and cytokines in response to a variety of stimuli that can have both autocrine and paracrine effects. All cells also secrete a range of cell adhesion molecules that are essential to cellular attachment to the tubular basement membrane.

Regulatory Function

The kidneys regulate and maintain the constant optimal chemical composition of the blood and the interstitial and intracellular fluids throughout the body. The mechanisms of differential reabsorption and secretion, located in the tubule of a nephron, are the effectors of regulation. The mechanisms operate under a complex system of control in which both extrarenal and intrarenal humoral factors participate.

Electrolyte Homeostasis

There is a complex interplay between the tubular transport systems regulating individual electrolytes. For simplicity, we have considered each electrolyte individually and have restricted our discussion to the systems of major physiological, pharmacological, and pathological significance.

Sodium

Sodium reabsorption is required for the reabsorption of water and many solutes. The proximal tubule is highly permeable to sodium, and the net flux of reabsorption from the tubular lumen is achieved against a high backflux, particularly from paracellular movement. Approximately 60% of filtered sodium is reabsorbed in the proximal tubule in an energy-dependent manner, driven by basolateral Na^+, K^+-ATPase pumps. Approximately 80% of sodium entering proximal tubular cells does so in exchange for hydrogen ion secretion, facilitated by apical sodium-hydrogen exchangers. This in turn permits bicarbonate reabsorption via carbonic anhydrases that are present in both the brush border and intracellular compartment. A variety of apical sodium co-transporters also allow for reabsorption of other organic and inorganic solutes (e.g., chloride, calcium, phosphates, bicarbonate, sulfates,[390] glucose, urea, and amino acids). Sodium transport activity is regulated by many factors, including protein kinase–dependent phosphorylation, which can increase both activity and channel numbers.

A further 30% of filtered sodium is reabsorbed in the thick ascending limb of the loop of Henle, where it is achieved by an apical, bumetanide-sensitive, 130 kDa, electroneutral, Na^+-K^+-$2Cl^-$ co-transporter (NKCC2), itself driven by a favorable inward gradient generated by the basolateral Na^+, K^+-ATPase pump (Figure 45-7). NKCC2 is a

*Certain substances, almost completely reabsorbed by the tubules when their concentrations in plasma are relatively low, appear in the urine when their plasma levels are above a certain set-point or "threshold" level. Creatinine, which is reabsorbed only minimally, is a low-threshold substance. High-threshold substances, such as glucose and amino acids (whose conservation is important to the body economy), are almost completely reabsorbed by means of specific transport systems in the tubular cells. The appearance of a high-threshold substance in the urine is evidence that the filtered load of the substance is exceeding the maximal reabsorption rate of its transport system. This may occur when the filtered load is excessive owing to elevated plasma concentration or to rapid urine flow; alternatively, the defect may be in the transport system and related to chemical inhibitors, injury to tubular epithelial cells, or genetic defects in the system. The renal threshold of a filterable compound is therefore that plasma concentration of the substance at which the tubular reabsorptive rate, operating at maximum, is not sufficiently fast to remove all of the substance from the plasma ultrafiltrate so that the substance "spills" into the urine.

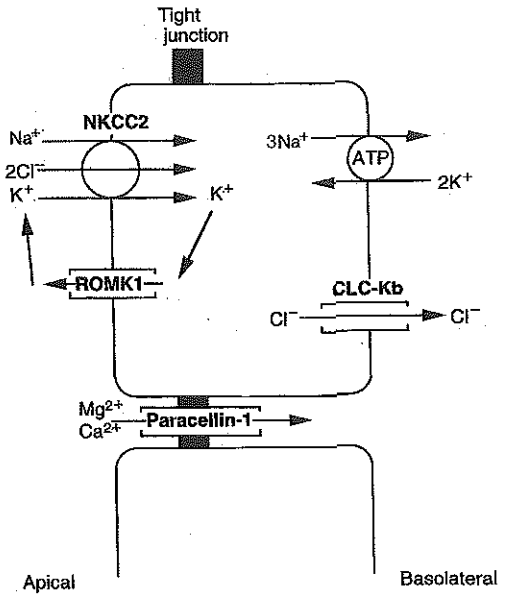

Figure 45-7 Schematic diagram showing the major pathways of solute reabsorption in the thick ascending limb of the loop of Henle. Sodium chloride is reabsorbed by the apical NKCC2 transporter. This electroneutral transport is driven by the low intracellular sodium and chloride concentrations generated by the basolateral Na^+, K^+-ATPase and the basolateral chloride channel CLC-Kb. The availability of potassium is rate-limiting for NKCC2, so potassium entering the cell is recycled back to the lumen via the ROMK1 potassium channel. This potassium movement is electrogenic and drives paracellular resorption of Mg^{2+} and Ca^{2+} via paracellin-1. Mutations in either NKCC2, ROMK1, or CLC-Kb cause Bartter's syndrome. Mutations in paracellin-1 lead to disruption of this paracellular pathway and the tubular disease known as hypomagnesemic hypercalciuric nephrolithiasis. *(From Sayer JA, Pearce SHS. Diagnosis and clinical biochemistry of inherited tubulopathies. Ann Clin Biochem 2001;38:459-70.)*

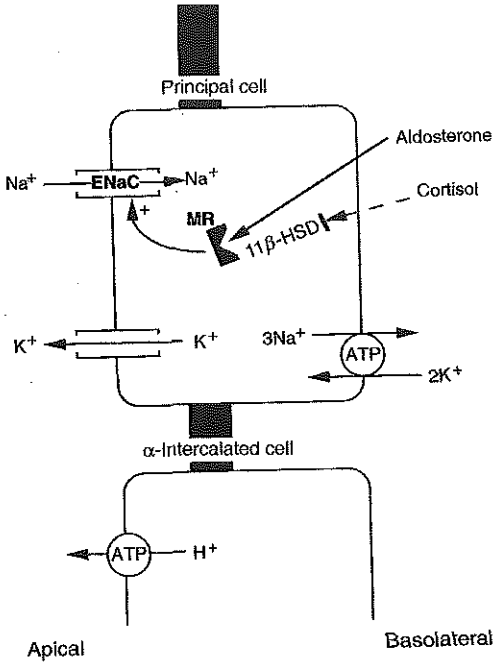

Figure 45-8 Schematic diagram showing the major pathways of solute reabsorption in the collecting duct. In principal cells, sodium reabsorption occurs through the amiloride-sensitive epithelial sodium channel (ENaC). This is influenced by the actions of aldosterone on the mineralocorticoid receptor (MR), with hyperaldosteronism producing an increase in channel activity. Cortisol, if permitted, will also bind to the MR, but a degree of specificity is maintained by 11β-hydroxysteroid dehydrogenase (11β-HSD), which inactivates cortisol to cortisone. Sodium uptake drives potassium secretion from principal cells and proton secretion from α-intercalated cells. In Liddle's syndrome, mutations lead to an increase in ENaC activity, with increased Na^+ reabsorption and consequent potassium and proton loss. In pseudohypoaldosteronism type Ia, loss of function mutations inactivates ENaC, whereas in pseudohypoaldosteronism type Ib there are MR abnormalities. Both lead to reduced sodium entry via ENaC, causing salt wasting and decreased secretion of potassium and protons. Licorice causes hypertension and a hypokalemic metabolic alkalosis by inactivating 11β-HSD, allowing cortisol to act as a mineralocorticoid. *(From Sayer JA, Pearce SHS. Diagnosis and clinical biochemistry of inherited tubulopathies. Ann Clin Biochem 2001;38:459-70.)*

kidney-specific member of a class of such channels found throughout secretory epithelia. Activation of these co-transporters appears, in part, to be a result of cell shrinkage. The distal tubule reabsorbs 5% to 8% of sodium via the thiazide-sensitive Na^+-Cl^- co-transporter (NCCT). Final sodium balance is achieved in the collecting duct via selective amiloride-sensitive, apical sodium channels (ENaCs) in exchange for potassium. ENaCs are controlled in part by the effects of aldosterone on the mineralocorticoid receptor (Figure 45-8).

Potassium

Approximately 90% of daily potassium loss occurs via renal elimination. Potassium is freely filtered across the glomerulus and normally almost completely reabsorbed in the proximal tubule. However, most regulatory mechanisms affect the loop of Henle, the distal tubule, and the collecting duct. Indeed, urinary losses can exceed filtered load, indicating the importance of distal secretion. Determinants of urinary potassium loss are dietary intake of potassium, acid-base disturbances (acidosis reduces potassium secretion and vice versa), plasma potassium concentration, circulating ADH concentration, tubular flow rate, and aldosterone secretion (enhances potassium loss and increases sodium retention).[135] Potassium ions are actively accumulated within tubular cells as a result of basolateral Na^+, K^+-ATPase activity, resulting in elevation of intracellular potassium concentration above its electrochemical equilibrium. Several types of potassium channels exist that have a range of functions: (1) maintenance of a negative resting cell membrane potential, (2) regulation of intracellular volume, (3) recycling of

K^+ across apical and basolateral membranes to supply NKCC2 and enable sodium reabsorption, and (4) K^+ secretion in the cortical collecting tubule.[25] As mentioned above, potassium is reabsorbed with sodium by the NKCC2 in the thick ascending limb of the loop of Henle, but is recycled back into the lumen by the potassium-secreting channel ROMK1. This process is electrogenic and drives paracellular reabsorption of calcium and magnesium (see Figure 45-7). ROMK1 is a pH-sensitive, membrane-spanning protein with several serine residues. At least two of these residues require phosphorylation by protein kinase A for the channel to be active.[25]

In the principal cells of the collecting duct, sodium reabsorption via ENaC is accompanied by movement of potassium into the lumen through potassium channels or a potassium chloride symporter (see Figure 45-8).

Chloride

The intracellular negative electrical potential opposes chloride entry into cells. In the early proximal tubule the main cation, sodium, is predominantly reabsorbed concomitantly with bicarbonate so that the luminal chloride concentration actually increases. There are two main reabsorption mechanisms for chloride. The first is via an antiporter in exchange for secretion of other anions (e.g., bicarbonate) or formate. The second occurs in the final two thirds of the proximal tubule. In the thick ascending limb of the loop of Henle, chloride is reabsorbed in association with sodium via NKCC2. The concentration gradient is maintained by a basolateral chloride pump, CLC-Kb (see Figure 45-7). A further chloride channel, CLC-5, is expressed at multiple sites in the nephron.[410]

Calcium

Approximately 98% of filtered calcium is reabsorbed: 65% to 75% in the proximal tubule (via a paracellular pathway), 20% to 25% in the thick ascending limb of the loop of Henle, 10% in the distal tubule, and finally small amounts in the collecting ducts.[75] This is predominantly a passive process linked to active sodium reabsorption. For example, in the thick ascending limb of the loop of Henle, paracellular calcium transport is driven by the potential difference created by ROMK1. There are also active processes, particularly in the distal tubule, that tightly regulate the final amount of calcium excreted. Here, calcium reabsorption is transcellular and is predominantly under the control of parathyroid hormone (PTH) and the calcium-sensing receptor. Following entry into the cell from the lumen via an apical epithelial active transport mechanism (ECaC1), calcium binds to calbindin-D and is delivered to the basolateral membrane. Here it is extruded by a Ca^{2+}-ATPase (PMCA1b) and a sodium-calcium exchanger (NCX1).[289] Transcription of both ECaC1 and calbindin is stimulated by calcitriol ($1,25(OH_2)D_3$), possibly synthesized locally in the distal nephron and acting in a paracrine and autocrine fashion. A functional vitamin D response element has been identified in the promoter region of the calbindin-D gene and there is a putative site in the ECaC1 gene.[289] ECaC1 is a pH-sensitive, 83 kDa protein with six transmembrane-spanning domains. Activation of the ion channel probably involves protein kinase C phosphorylation.[289] There is evidence that stimulation of the renal calcium-sensing receptor can directly affect tubular reabsorption of calcium, independent of the effects of calciotropic hormones.

Phosphate

Reabsorption of phosphate occurs predominantly in the proximal tubule and is mediated by a secondary-active transport mechanism. Three families (types I, II, and III) of sodium-dependent/phosphate co-transporters have been identified, of which the type IIa, a 640 amino acid protein located in the apical plasma membrane, is thought to be the most physiologically important. Type IIa sodium-phosphate transport is electrogenic (i.e., involves the inward flux of a positive charge), with three sodium ions and one phosphate ion (preferentially divalent) being transferred. Acute regulation of transport is primarily achieved by an alteration in the amount of type IIa protein present in the apical membrane, with longer-term changes also involving increased transcription of the protein (e.g., in response to $1,25(OH_2)D_3$). Tonic levels of type IIa in the apical membrane are thought to be high, with regulation predominantly involving internalization of the protein. Increased trafficking of the channel from the plasma membrane to the lysosomes is believed to follow both protein kinase A and C phosphorylation initiated by PTH receptor binding. Efflux of phosphate across the basolateral membrane may involve an anion exchange mechanism and/or a phosphate leak.[408]

Normally less than 20% of the filtered load of phosphate is excreted into the urine, but above a plasma phosphate concentration of approximately 1.2 mmol/L increments in urinary phosphate excretion increase linearly with the filtered load, suggesting that there is T_m (tubular maximal uptake) for phosphate.[290] Predictably the T_m for phosphate is influenced by the circulating PTH concentration and the ratio of T_m for phosphate to GFR (T_mP/GFR). T_mP/GFR has been used as a test in the differential diagnosis of hypercalcemia. Although superseded in this context by modern PTH assays, it may still be useful in the investigation of inherited disorders of tubular phosphate handling.[320]

Bicarbonate and Hydrogen Ion

The kidney plays a central role in the maintenance of acid-base homeostasis through reclamation of filtered bicarbonate and secretion of ammonium and acid. The tubular mechanisms underlying these processes are discussed in Chapter 46.

Water Homeostasis

The production of glomerular filtrate normally amounts to about 180 L/day. The unique physiology of the kidney enables approximately 99% of this to be reabsorbed in the

production of a urine with variable osmolality: between 50 and 1400 mOsmol/kg/H_2O at extremes of water intake. Plasma membranes of all mammalian cells are water permeable but to variable degrees. In the kidney, different segments of the nephron show differing permeability to water, enabling the body to both retain water and produce a urine of variable concentration. This process occurs both isosmotically, in association with electrolyte reabsorption in the proximal tubule, and differentially, in the loop of Henle, distal tubule, and collecting duct in response to the action of the nonapeptide ADH. Absorption of water depends on the driving force for water reabsorption (predominantly active sodium transport) and the osmotic equilibration of water across the tubular epithelium. The generation of concentrated urine depends upon medullary hyperosmolality, which in turn requires low water permeability in some kidney segments (ascending limb of the loop of Henle), whereas in other kidney segments there is a requirement for high water permeability. In recent years our understanding of the molecular mechanisms underlying water reabsorption has increased: differing permeability and the enaction of hormonal control appear to be largely caused by the differential expression along the nephron of a family of proteins known as the aquaporins (AQP), which act as water channels.

At least 11 different mammalian AQP have now been identified, of which seven (AQP1, -2, -3, -4, -6, -7, -8) are expressed in the kidney.[299,300] Many of these also have extrarenal expression sites (e.g., AQP1 may be important in fluid removal across the peritoneal membrane). Two asparagine-proline-alanine sequences in the molecule are thought to interact in the membrane to form a pathway for water translocation. AQP1 is found in the proximal tubule and descending thin limb of the loop of Henle and constitutes almost 3% of total membrane protein in the kidney. It appears to be constitutively expressed and is present in both the apical and basolateral plasma membranes, representing the entry and exit ports for water transport across the cell, respectively. Approximately 70% of water reabsorption occurs at this site, predominantly via a transcellular (i.e., AQP1) rather than a paracellular route. Water reabsorption in the proximal tubule passively follows sodium reabsorption, so that the fluid entering the loop of Henle is still almost isosmotic with plasma.

Urinary concentration is predominantly achieved by countercurrent multiplication in the loop of Henle (Figure 45-9).[347,367] Although the descending thin limb is very permeable to water, the ascending limb and the collecting duct are not (the collecting ducts are also poorly permeable to urea). The fluid entering the loop of Henle is isotonic to plasma but is hypotonic on leaving it. The ascending limb has active sodium reabsorption driven by Na^+, K^+-ATPase with electroneutralizing transport of chloride, a combined process that can be inhibited by the so-called loop diuretics (e.g., furosemide, see discussion later in this chapter). In this section of the nephron, sodium reabsorption is not accompanied by water, creating a hypertonic medullary interstitium and facilitating water reabsorption from the anatomically adjacent descending limb. The descending limb cells are permeable to sodium chloride, which is cycled from the descending limb back to the ascending limb. The continuous flow along the loop generates an osmotic gradient at the tip of the loop that can reach 1400 mOsmol/kg/H_2O. Approximately 5% of water is reabsorbed in the loop of Henle.

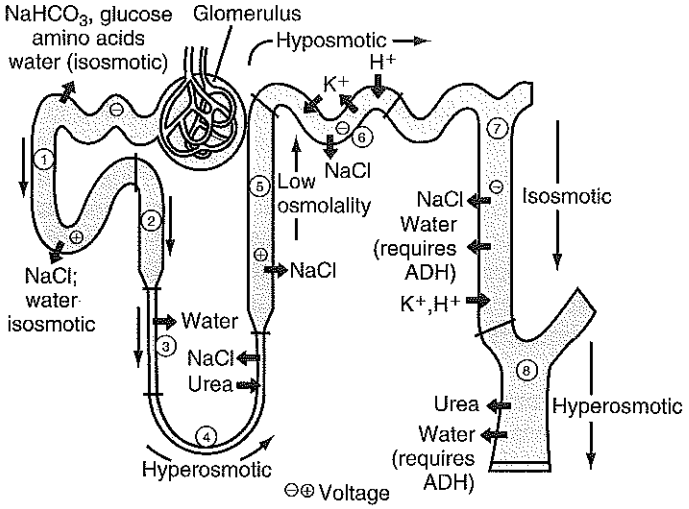

Figure 45-9 Countercurrent multiplication mechanism: schematic representation of the principal processes of transport in the nephron. In the convoluted portion of the proximal tubule *(1)*, salts and water are reabsorbed at high rates in isotonic proportions. Bulk reabsorption of most of the filtrate (65% to 70%) and virtually complete reabsorption of glucose, amino acids, and bicarbonate take place in this segment. In the pars recta *(2)*, organic acids are secreted and continuous reabsorption of sodium chloride takes place. The loop of Henle comprises three segments: the thin descending *(3)* and ascending *(4)* limbs and the thick ascending limb *(5)*. The fluid becomes hyperosmotic, because of water abstraction, as it flows toward the bend of the loop, and hyposmotic, because of sodium chloride reabsorption, as it flows toward the distal convoluted tubule *(6)*. Active sodium reabsorption occurs in the distal convoluted tubule and in the cortical collecting tubule *(7)*. This latter segment is water-impermeable in the absence of ADH, and the reabsorption of sodium in this segment is increased by aldosterone. The collecting duct *(8)* allows equilibration of water with the hyperosmotic interstitium when ADH is present. For further details, see text. *(From Burg MB: The nephron in transport of sodium, amino acids, and glucose. Hospital Practice 1978;13:100. Adapted from a drawing by A. Iselin.)*

A further 10% of water reabsorption occurs in the distal tubule, with the remainder (more than 20 L/day) being reabsorbed in the collecting ducts. Entry of water into the collecting duct cells occurs via apical AQP2 channels, with exit probably occurring via basolateral AQP3 (cortical and outer medullary collecting ducts) and AQP4 (inner medullary collecting ducts). AQP2 appears to be the primary target for ADH regulation of water reabsorption. AQP2 is stored in subapical vesicles in the collecting duct cells. In response to

ADH stimulation these vesicles are cycled through, and inserted into, the plasma membrane by a cytoskeletal, dynein-mediated, transport process. ADH stimulation occurs following binding of ADH to a V_2 receptor in the plasma membrane, which stimulates a cAMP/protein kinase A cascade resulting in phosphorylation and activation of AQP2. ADH regulates the acute cellular water-retaining response (AQP2 trafficking) and also its longer-term regulation, via a conditioning effect on AQP2 gene transcription. It is likely that there are also ADH-independent regulatory pathways of AQP2 expression. Membrane insertion of AQP2 allows water to pass into the collecting duct cells under the influence of medullary hyperosmolality. Maintenance of medullary hyperosmolality also depends upon efficient fluid removal, which is the function of the ascending vasa recta, a specialized medullary vasculature, and the close anatomical relations of all the medullary constituents (see Figure 45-2). AQP2 expression is decreased in a variety of polyuric conditions (e.g., diabetes insipidus, lithium treatment, hypokalemia, hypercalcemia, urinary obstruction) and increased in some water-retaining states (e.g., heart failure and pregnancy).[300]

ADH also increases the permeability of collecting duct cells to urea, which is the major osmotically active component of the luminal fluid in the distal tubule. Fluid of high urea concentration therefore enters the deepest layers of the medullary interstitium, passing down its concentration gradient, contributing to medullary hyperosmolality. The regulation of ADH excretion is of vital importance to fluid homeostasis. The normal plasma osmolality is maintained very tightly between 280 and 290 mOsmol/kg/H_2O and is regulated by means of specific osmoreceptors found in the anterior hypothalamus. These receptors modulate the release of ADH and also affect thirst. ADH release may also be stimulated by hypotension, hypovolemia, and vomiting independently of osmoregulation.

Endocrine Function

The *endocrine functions* of the kidneys may be regarded either as primary, because the kidneys are endocrine organs producing hormones, or as secondary, because the kidneys are a site of action for hormones produced or activated elsewhere. In addition, the kidneys are a site of degradation for hormones such as insulin and aldosterone. In their primary endocrine function, the kidneys produce erythropoietin (EPO), prostaglandins and thromboxanes, renin, and $1,25(OH_2)D_3$.

Erythropoietin

Erythropoietin is a a glycoprotein hormone secreted chiefly by the kidney in the adult and by the liver in the fetus that acts on the bone marrow cells to stimulate erythropoiesis. It is an α-globulin having a molecular weight of 38 kDa. Physiologically the kidneys sense a reduction in O_2 delivery to tissues by blood and release erythropoietin, thereby stimulating the bone marrow to make more RBCs. Conversely, with a surplus of O_2 in blood traversing the kidneys, as in some forms of polycythemia, the release of erythropoietin into blood is diminished. The use of recombinant human erythropoietin (rhEPO, Epoetin) in the management of anemia of kidney disease is discussed below.

Prostaglandins and Thromboxanes

Prostaglandins and thromboxanes are synthesized from arachidonic acid by the cyclooxygenase enzyme system (see Chapter 26 for further details). This system is present in many parts of the kidney and has an important role in regulating the physiological action of other hormones on renal vascular tone, mesangial contractility, and tubular processing of salt and water. In pathophysiological circumstances, such as acute glomerulonephritis and various forms of acute renal failure, thromboxane A_2 and various prostaglandins may have a significant role in inflammation and alteration of vascular tone. The effects of nonsteroidal antiinflammatory drugs (NSAIDs) on renal prostaglandin metabolism are considered later in this chapter. The lipoxygenase pathway, which leads to formation of leukotrienes, is also present within the kidneys, although the major source of leukotrienes in inflammatory disease of the kidneys is infiltrating white cells and macrophages.

Renin

Renin is an enzyme of the hydrolase class that catalyzes cleavage of the leucine-leucine bond in angiotensinogen to generate angiotensin I.[93] The enzyme is synthesized as inactive prorenin in the kidney and released into the blood in the active form in response to various metabolic stimuli. The importance of renin in the maintenance of systemic blood pressure was discussed previously (see Juxtaglomerular Apparatus).

$1,25(OH_2)D_3$

The kidneys are primarily responsible for producing $1,25(OH_2)D_3$ from 25-hydroxycholecalciferol as a result of the action of the enzyme 25-hydroxycholecalciferol 1α-hydroxylase found in proximal tubular epithelial cells. The regulation of this system is considered in Chapter 49. The management of renal osteodystrophy is considered later in this chapter.

Glomerular Filtration Rate

The GFR is considered to be the most reliable measure of the functional capacity of the kidneys and is often thought of as indicative of the number of functioning nephrons. As a physiological measurement, it has proved to be the most sensitive and specific marker of changes in overall renal function. Measurement of GFR is discussed in Chapter 24.

The rate of formation of the glomerular filtrate depends upon the balance between hydrostatic and oncotic forces along the afferent arteriole and across the glomerular filter. The net pressure difference must be sufficient not only to

TABLE 45-3 Summary of Factors That Influence the Glomerular Filtration Rate (See text for explanation of terminology)

	Major Influencing Factors	Effect on GFR
K_f	Increased glomerular surface area due to relaxation of mesangial cells	Increase
	Decreased glomerular surface area due to contraction of mesangial cells	Decrease
P_{GCap}	Altered renal arterial pressure	
	Afferent dilation	Increase
	Afferent constriction	Decrease
	Efferent constriction	Increase
	Efferent dilation	Decrease
P_{BC}	Increased intratubular pressure (e.g., tubular obstruction)	Decrease
Π_{GCap}	Altered plasma oncotic pressure: increased	Decrease
	Altered renal blood flow: decreased	Decrease

drive filtration across the glomerular filtration barrier but also to drive the ultrafiltrate along the tubules against their inherent resistance to flow. In the absence of sufficient pressure the lumina of the tubules will collapse. This balance of forces can be expressed as follows:

$$\text{Rate of filtration} = K_f((P_{GCap} + \Pi_{BC}) - (P_{BC} + \Pi_{GCap}))$$

Where

K_f = (hydraulic permeability × surface area)
P_{GCap} = glomerular-capillary hydrostatic pressure
Π_{BC} = oncotic pressure* in Bowman's capsule
P_{BC} = hydrostatic pressure in Bowman's capsule
Π_{GCap} = oncotic pressure in the glomerular capillary

As the oncotic pressure in Bowman's capsule (Π_{BC}) can be considered to be negligible (protein concentration is usually 10 to 100 mg/L), this equation becomes:

$$\text{Rate of filtration} = K_f(P_{GCap} - P_{BC} - \Pi_{GCap})$$

Changes in K_f can be caused by drugs and by glomerular disease, but it is also physiologically regulated. Mesangial cell contraction is thought to be the main mechanism and causes a reduction in K_f, tending to reduce GFR. Net P_{GCap} represents a balance between renal arterial pressure and afferent and efferent arteriolar resistance. Although an increase in arterial pressure will tend to increase P_{GCap}, the magnitude of the change is modulated by differential manipulation of afferent and efferent tone, which can result in minimal change to the P_{GCap}. When the renal blood flow is low, oncotic pressure can change as the plasma passes along the renal capillaries. As filtrate is removed, the oncotic pressure rises, and by the end of the capillary the net filtration rate may become zero; thus GFR falls, and this limits the amount of filtrate that can be obtained from a given volume of plasma. The average ($P_{GCap} - P_{BC} - \Pi_{GC}$) or net filtration pressure is only about 17 mm Hg. This pressure is sufficient to drive the filtration of 180 L of fluid per day only because the K_f for glomerular capillaries is several orders of magnitude greater than for nonrenal capillaries.

Oncotic pressure is defined in *Dorland's Illustrated Medical Dictionary* as the "osmotic pressure due to the presence of colloids in a solution.[93]"

Regulation of GFR

The factors involved in regulation of GFR are listed in Table 45-3. Autoregulation of renal blood flow and GFR is widely thought to be explained by the *myogenic theory.* This theory is based on the principle that an increase in the wall tension of the afferent arterioles, brought about by an increase in perfusion pressure, causes automatic contraction of the arteriolar smooth muscle, thus increasing resistance and keeping the flow constant despite the increase in perfusion pressure.

The *tubuloglomerular feedback mechanism,* involving the macula densa and release of the vasodilator adenosine, must also be considered. Although not fully understood, this mechanism appears to regulate GFR, with changes in renal blood flow as a secondary consequence. For individual nephrons, there is evidence that each single nephron GFR (SNGFR) is influenced by the composition of the tubular fluid in the distal tubule, which in turn is influenced by the filtration rate. The macula densa is thought to sense either the distal tubular sodium chloride content, its osmolality, or the rate at which sodium chloride is transported. The macula densa then signals the JGA via an uncertain mechanism to cause the release of adenosine and possibly AII and prostaglandins, which in turn affect vascular tone.

The result of the combination of myogenic mechanisms and tubuloglomerular feedback is that the net filtration pressure or P_{GCap} is kept reasonably constant over a very wide range of systemic arterial pressures. It should be noted that renal blood flow and GFR change across this range of systemic pressures but to a significantly smaller extent than would be predicted if these autoregulatory mechanisms were not in place.

TABLE 45-4 Factors Altering Renal Artery Tone and Renal Blood Flow

	Effect on:		Effect on:	
Factor	**Afferent Arteriole**	**Efferent Arteriole**	**RBF**	**GFR**
Adenosine	Constriction	Dilation	N	N → NE
Angiotensin II	Constriction	Constriction	N	N
Epinephrine/norepinephrine	Constriction	Constriction	N	N → NE
Antidiuretic hormone (ADH)	Constriction	Constriction	NE	N → NE
Endothelin	Constriction	Constriction	NE	N → NE
Leukotrienes	Constriction	Constriction	NE	N → NE
Thromboxane A_2	Constriction	Constriction	NE	N → NE
Prostaglandins (PGE_2, PGI_2)	Dilation	Dilation	NE	NE
Nitric oxide	Dilation	Dilation	N	N
Atrial natriuretic factor	Dilation	Constriction	N	N → P
Dopamine	—	Dilation	N	N

NE, Negligible; *N*, negative; *P*, positive; *RBF*, renal blood flow; *GFR*, glomerular filtration rate.

Other factors influencing renal blood flow are indicated in Table 45-4. The afferent and efferent arterioles are richly supplied with renal sympathetic nerves. Epinephrine acts via α-adrenergic receptors to cause constriction of both arterioles, causing a decrease in renal blood flow.

Nitric oxide (NO) has been identified as an important vasodilator produced by vascular endothelial cells. NO is synthesized from L-arginine and oxygen by nitric oxide synthetase (NOS), of which there are three isoenzymes differentially located and regulated. Within the kidney, there are eNOS (endothelial) and iNOS (inducible) isoenzymes. Activation of NOS has been shown to occur as a result of shear stress (e.g., increased arteriolar tone). There are a variety of physiological vasoconstrictors, including acetylcholine, bradykinin, endothelin, and serotonin; a rise in intracellular ionized calcium is required for the vasoconstrictors. NO synthesis is now known to play an important role in the regulation of human vascular tone and has a crucial role in control of blood pressure and kidney function.[92,143,342] It has also been found in the macula densa and has been implicated in the regulation of renin release. However, NO has an unpaired electron, and it can be oxidized by superoxide to peroxynitrite, which is further metabolized to nitrite and nitrate anions. It has been suggested that the physiological balance between superoxide and NO is important to the regulation of vascular tone.

Age and GFR

Kidney function is not constant throughout life. In utero, urine is produced by the developing fetus from about the ninth week of gestation. Nephrogenesis is complete by approximately 35 weeks gestation, although kidney function remains immature during the first 2 years of life. The kidney of the term infant receives approximately 6% of the cardiac output, compared with 25% in adults.[134] Renal vascular resistance is relatively high and the low renal blood flow is particularly directed to the medulla and inner cortex. The gradual increase in renal blood flow that occurs with increasing age is mainly directed to the outer cortex and is mediated by local neurohormonal mechanisms.[198] The GFR at birth is approximately 30 mL/min/1.73 m^2.[70] It increases rapidly during the first weeks of life to reach approximately 70 mL/min/1.73 m^2 by age 16 days.[70] Normal adult values are achieved by age 14. Tubular functions, including salt and water conservation, are also immature at birth. Birth is associated with rapid changes in kidney function, with a switch to salt and water conservation being mediated by catecholamines, the renin-angiotensin system, vasopressin, glucocorticoids, and the thyroid hormone.[70] The immaturity of the neonatal kidney contributes to the relatively common problems of water and electrolyte disturbances in infants. These disturbances are more likely to occur in premature infants, particularly those born before 35 weeks gestation.

Aging is associated with a range of structural changes in the kidney, including decreasing weight, total renal area, cortical area, and number of glomeruli.[99] The percentage of sclerotic glomeruli increases, particularly in the cortical zone.[207] These changes are paralleled by changes in the afferent and efferent arteriolar systems, with sclerosis of the cortical systems and the formation of direct channels (shunts) between the afferent and efferent arterioles in the medulla. Aging is also associated with the development of tubulointerstitial fibrosis, loss of tubular mass, and decreasing length of the proximal tubule.

Structural change is accompanied by functional changes, which in many respects are the reverse of those seen in early life. On average, GFR declines with age by approximately 1 mL/min/1.73 m^2/yr over the age of 40[9,82,439] and the rate of decline in GFR accelerates after age 65.[360] Renal blood flow also decreases with age, while the filtration fraction (i.e., GFR/renal plasma flow)[9] and renal vascular resistance[107,108]

increase. Blood flow to the renal cortex would appear to be particularly affected. The higher filtration fraction of the deeper juxtamedullary glomeruli may in part explain the increase in filtration fraction with aging: this may be an adaptive response to structural change helping to preserve kidney function in the aging individual.[244] In healthy older people, renal functional reserve including the acute renal vasodilatory response to an amino acid infusion appears to be retained.[108] Tubular function, such as the ability to concentrate urine and excrete a water and salt load, is decreased and nocturnal polyuria is common. Renal salt conservation is also impaired[99] and urinary albumin excretion increases with age.[167,195]

It is not known whether these changes are the result of a normal aging process (i.e., involutional) or the result of the interplay of pathology and age. Cumulative exposure to common causes of chronic kidney disease (CKD), such as (1) atherosclerosis, (2) hypertension, (3) heart failure, (4) diabetes,[66] (5) obstructive nephropathy, (5) infection, (6) immune insult, (7) nephrotoxins such as lead,[242] and (8) dietary protein[4,46] increases with age and it is difficult to separate these effects from those of "healthy" aging. The decline in GFR with increasing age may be largely attributable to hypertension,[245,246] atherosclerosis,[207] or heart failure.[106,120] In the absence of these or other identifiable causes of kidney disease, many older subjects have stable GFR over time.

Loss of kidney function with aging appears to be heterogeneous and is not inevitable.[107,244] Kidney function may be well preserved in healthy older people and assumptions with respect to GFR based solely on age could be erroneous. Conversely, attention to the common causes of CKD could preserve function in older people.[377] What is commonly not appreciated is that kidney failure is predominantly a disease of older people. Studies from England,[103] France,[201] and Iceland (Figure 45-10)[258] have demonstrated a near exponential rise in CKD with age. The incidence of acute renal failure (ARF) also increases with age.[213]

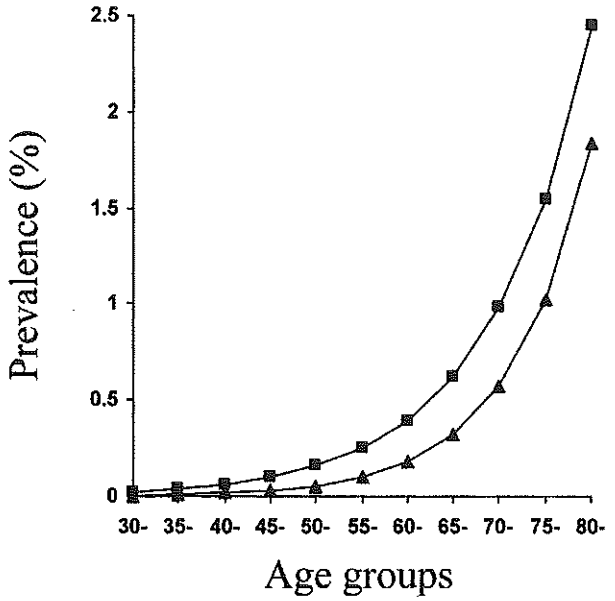

Figure 45-10 Prevalence of chronic renal failure (serum creatinine ≥150 μmol/L) in an Icelandic population according to age and sex, demonstrating the near exponential rise in prevalence with age. Curves were generated by logistic regression based on the prevalence in different age groups. Women (triangles), prevalence = $0.00016 \times 1.124^{age}$; men (squares), prevalence = $0.0016 \times 1.096^{age}$. *(Reproduced with permission from Magnason RL, Indridason OS, Sigvaldason H, Sigfusson N, Palsson R. Prevalence and progression of CRF in Iceland: a population-based study. Am J Kidney Dis 2002;40:955-63, with permission from the National Kidney Foundation.)*

Glomerular Permeability and Filtration

The glomerulus acts as a selective filter of the blood passing through its capillaries. The combination of a specialized endothelium, epithelial cell barrier, and basement membrane rich in negatively charged proteoglycans produces a filter that restricts the passage of macromolecules in a size-, charge-, and shape-dependent manner (see Figure 45-3, bottom). Various models of the basement membrane have been proposed to account for its performance; most important are the fiber-matrix and the pore theories.[36,79] It seems most likely that the fiber-matrix model is closest to reality, with fibers separated by interstices about 2 nm wide, pores not having been detected using electron microscopy. The basement membrane is a compressible filter, becoming more permeable as the applied pressure decreases and the fibers separate.[81,356]

The glomerular permeability of a molecule is expressed in terms of its glomerular sieving coefficient (GSC). Molecules smaller than approximately the molecular weight of inulin (5 kDa) are freely filtered. Therefore, inulin, urea, creatinine, glucose and electrolytes all have a GSC = 1.0. Classic experiments have used linear dextran chains of varying molecular weight and charge to study glomerular filtration characteristics. However, linear carbohydrate chains do not necessarily behave in the same manner as a globular protein of equal molecular weight or charge. For example, neutral dextran chains of 15 kDa (diameter 2.4 nm) have GSC = 1.0 whereas β_2-microglobulin (11.8 kDa, diameter 1.6 nm) has GSC = 0.7.[20] Linear molecules have higher GSC than globular proteins. Examples of the relationships between size, charge, and mass of the major urinary proteins and their glomerular handling are listed in Table 24-1.

The protein concentration in the glomerular filtrate has been measured in a number of animal models by direct glomerular puncture. The concentration of total protein found is in the range of several hundred mg/L (approximately 1% of plasma), with albumin concentrations ranging from a few hundred to less than 40 mg/L. The filtered load of protein depends on the product of the GSC and the free

TABLE 45-5 Characterization of Proteinuria

Type of Proteinuria	Causes	Examples of Proteins Seen
Glomerular	Increased glomerular permeability	Progressively increasing excretion of higher molecular weight proteins as permeability increases (e.g., albumin, IgG)
Overflow	Increased plasma concentration of relatively freely filtered protein	Bence Jones protein Lysozyme Myoglobin
Tubular	Proximal tubular damage: decreased tubular reabsorptive capacity and/or release of intracellular components (e.g., due to nephrotoxic drugs)	α_1-microglobulin β_2-microglobulin Retinol binding protein Enzymuria (e.g., *N*-acetyl-β-D-glucosaminidase, alkaline phosphatase, α-glutathione-S-transferase)
	Decreased nephron number: increased filtered load per nephron	As above
	Distal tubular damage	Tamm Horsfall glycoprotein π-glutathione-S-transferase

plasma concentration: therefore the albumin load per nephron is much greater than that of the other filtered proteins.[20,254] In general, proteins of molecular weights greater than albumin (66 kDa, diameter 3.5 nm) are retained by the healthy glomerulus and are termed high molecular weight proteins. However, lower molecular weight proteins are also retained to a significant extent.

The urinary concentration of proteins depends upon the filtered load and on the efficiency of the proximal tubular reabsorptive process. Proteins are reabsorbed by receptor-mediated, low-affinity, high-capacity processes. Megalin (600 kDa) and cubulin (460 kDa) are endocytic, multi-ligand receptors that are important in protein reabsorption.[434] Megalin belongs to the LDL-receptor family whereas cubulin is identical to the intestinal intrinsic factor-vitamin B_{12} receptor. In the kidney, both are localized in clathrin-coated pits in the apical brush border of renal proximal tubular cells and bind filtered proteins in a calcium-dependent process. Megalin appears capable of both binding and internalizing its ligands whereas the cubulin-ligand complex requires megalin to be internalized. Some proteins, such as albumin will bind to either receptor, whereas others are specific (e.g., transferrin binds to cubulin only, and retinol-binding protein (RBP) and α_1-microglobulin to megalin only). Once proteins have been internalized, they are transported by the endocytic vesicle and fuse with lysosomes. Proteolysis occurs and the resultant amino acids are released into the tubulointerstitial space across the basolateral surface of the tubular epithelial cell. The membrane vesicles are then recycled to the brush border to complete the reabsorption cycle.[272,289] In health, the reabsorptive mechanism removes 99% of the filtered protein, thus retaining most of their essential amino acid constituents for reuse.[20,144,254] Capture of filtered transport proteins is also important in conserving vitamin status (e.g., vitamin A associated with RBP). Tubular secretion of proteins also contributes to urinary total protein concentration: in particular, THG accounts for ~50% of urinary total protein. THG (200 kDa) is secreted into the tubular fluid only by the thick ascending limb and early distal convoluted tubule.[177] It is a major constituent of renal tubular casts along with albumin and traces of other proteins. The normal urinary total protein excretion is less than 150 mg/24 hours.

PROTEINURIA

The tubular reabsorptive process is saturable. Any increase in the filtered load (because of glomerular damage, increased glomerular vascular permeability [e.g., inflammatory response], or increased circulating concentration of low molecular weight proteins) or decrease in reabsorptive capacity (because of tubular damage) can result in increased urinary protein excretion (*proteinuria*). The pattern of urinary protein excretion can be used to identify the cause and to classify the proteinuria, of which there are three main types (Table 45-5).[169] Diagnostic approaches to the characterization of proteinuria are considered in Chapter 24.

Types of Proteinuria

The three main types of proteinuria are glomerular, overflow, and tubular proteinuria.

Glomerular Proteinuria

Any glomerular disease process may increase glomerular permeability as either a consequence of podocyte foot

process retraction and effacement or basement membrane damage from, for example, deposition of immune complexes or increased matrix protein deposition as in diabetic nephropathy, or both.[220,309] Increased glomerular permeability increases the filtered load of all proteins, but the most characteristic feature is the increasing amounts of the higher molecular weight proteins, such as albumin excreted into the urine.[13] As permeability increases, progressively larger proteins (e.g., IgG) will be excreted in larger amounts. The relative proportion of higher to lower molecular weight proteins has been used to define selective and nonselective proteinuria (Chapter 24).

Overflow Proteinuria

The selective increase in the urinary excretion of an individual low molecular weight protein suggests that its production rate, and thus plasma concentration, has increased dramatically without concomitant glomerular or tubular damage. Examples of this are the urinary excretion of Bence Jones protein in myeloma, lysozyme in some leukemias, and myoglobin in patients with rhabdomyolysis.

Tubular Proteinuria

Tubular proteinuria occurs as a result of decreased tubular reabsorptive capacity and/or tubular damage with essentially normal glomerular permeability. Proximal tubular cells may be damaged by toxic agents (e.g., drugs and heavy metals) or by anoxia, resulting in decreased reabsorption of filtered proteins and the loss of other tubular functions (e.g., electrolyte reabsorption). Lower molecular weight proteins (e.g., RBP, α_1-microglobulin)[8] appear in relatively higher amounts in the urine than albumin, producing a so-called tubular proteinuria pattern. Albumin itself also normally undergoes extensive tubular reabsorption. Why albumin excretion is not also increased in this setting is unclear, but it has been suggested that the endocytic uptake process is mediated by receptor(s) with differing affinities for different proteins (or classes of proteins), with albumin being preferentially reabsorbed.[298] Damage to tubular epithelial cells causes not only functional disturbances but also structural change, with increased cellular turnover and cell lysis resulting in the release of both brush border (e.g., alkaline phosphatase)[302] and lysosomal enzymes (e.g., *N*-acetyl-β-D-glucosaminidase).[199] This enzymuria provides a useful means of identifying tubular damage and may give different information from that obtained by monitoring functional changes in protein reabsorption.

CKD is invariably accompanied by a decrease in the number of viable nephrons. There is a compensatory increase in glomerular filtration in the remaining glomeruli, resulting in an increased filtered load of protein per nephron. In the absence of glomerular permeability changes, this will also give a tubular protein pattern.

Leakage of various plasma proteins into the urinary space as a result of tubulointerstitial damage caused by conditions such as inflammation may also occur. This can cause hematuria and proteinuria in the absence of glomerular permeability or tubular reabsorption changes.

Investigation and Consequences of Proteinuria

Investigation for increased urinary protein excretion is mandatory in any patient with suspected kidney disease. Clinical or overt proteinuria is often detected using dipstick methods, the detection limit of which is 200 to 300 mg/L. Diagnostic approaches to the investigation of proteinuria are discussed in Chapter 24. Proteinuria above 300 mg/day is generally pathological. However, there are exceptions to this. Proteinuria can occur as a result of fever and exercise (functional) or related to posture (orthostatic).[204,265] These sporadic changes can cause interpretative difficulties when pathology is suspected. Upright posture increases protein excretion in both normal subjects and those with kidney disease. If it is postural, disappearing during recumbency and absent from early morning samples, the patient can be strongly reassured.[399] In these benign situations, the level of proteinuria rarely exceeds 1000 mg/day. Proteinuria above 1000 mg/day implies glomerular proteinuria. Glomerular proteinuria may be heavy and a mixed proteinuria with the elevation of both high and low molecular weight proteins may be observed.

It is increasingly accepted that proteinuria is not just a consequence of, but contributes directly to, progression of kidney disease. The accumulation of proteins in abnormal amounts in the tubular lumen may trigger an inflammatory reaction, which in turn may contribute to interstitial structural damage and expansion, and progression of kidney disease.* Evidence gathered from in vitro studies suggests that glomerular filtration of an abnormal amount or types of protein induces mesangial cell injury, leading to glomerulosclerosis, and that these same proteins can also have adverse effects on proximal tubular cell function.[97] Numerous studies have demonstrated that proteinuria is a potent risk marker for progression of renal disease in both nondiabetic† and diabetic[176] kidney disease. Furthermore, reducing protein excretion slows the rate of progression of proteinuric kidney disease. This has been observed in clinical trials in patients treated with angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs), either alone or in combination.‡ These drugs reduce protein excretion by reducing intraglomerular filtration pressure and possibly by stabilizing the glomerular epithelial cell slit diaphragm proteins.[5,255] Consequently, reduction of proteinuria is an important therapeutic target.[189,209]

PATHOPHYSIOLOGY OF KIDNEY DISEASE

Despite the diverse initial causes, kidney disease that progresses to end-stage renal disease (ESRD) is a remarkably

*References 22, 33, 50, 100, 353, 373.
†References 56, 95, 190, 217, 361, 454.
‡References 19, 127, 217, 292, 317, 336, 362, 363.

monotonous process that is characterized by the relentless accumulation and deposition of extracellular matrix leading to widespread tissue fibrosis. Although correlation studies strongly suggest proteinuria to be a determinant in the progression of kidney failure, the mechanisms involved in its potential role of causing interstitial inflammation and scarring remain unresolved. Evidence gathered from in vitro studies suggests that filtration of an abnormal amount or type of protein by the damaged glomerulus may induce mesangial cell injury, leading to glomerulosclerosis, and that these same proteins can also have adverse effects on proximal tubular cell function.[97] Nephrons are lost via toxic, anoxic, or immunological injury that may initially injure the glomerulus, the tubule, or both together. Glomerular damage can involve endothelial, epithelial, or mesangial cells, and/or the basement membrane. Inflammatory stimuli are released including both cytokines and growth factors, such as transforming growth factor beta (TGF-β), interleukin-6 (IL-6), interferon-γ (INF-γ), or tissue necrosis factor-α (TNF-α); these inflammatory factors activate resident lymphocytes and macrophages and recruit additional cells from the peripheral circulation (see Chapter 22). Thus, cellular infiltration is a common but not universal finding in renal biopsy specimens. These activated cells can cause T-cell–mediated cell lysis, activation, and proliferation of interstitial fibroblasts. Fibroblast activity results in increased extracellular matrix synthesis and eventually glomerular and tubular fibrosis. The extracellular matrix expansion causes disruption of local blood flow, exaggerating regional ischemia, and a vicious cycle of inflammation, fibrosis, and cell death is propagated.

The kidneys have considerable ability to increase their functional capacity in response to injury. Thus, a significant reduction in functioning renal mass (50% to 60%) may occur before the onset of any significant symptoms or even before any major biochemical alterations appear. The most sensitive and specific measure of functional change is the GFR, which can be reduced to less than 60 mL/min/1.73 m^2 (Table 45-6) before signs and symptoms of kidney failure will be observed. This increase in workload per nephron is thought to be an important cause of progressive renal injury.[469] A well-recognized hypothesis suggests that independent of the primary renal injury, a point is reached in the decline in nephron number when further loss becomes inevitable and progressive as a consequence of a common pathway leading to interstitial fibrosis.[51,53,350] The elucidation of this common pathway is incomplete but is the focus of considerable research interest. Several animal models have been used to investigate mechanisms leading to fibrosis. It has been demonstrated that there is increased production and activity of TGF-β in glomerular disease, and this acts as a key mediator, along with angiotensin, of fibrogenesis.[40,369,464] Data support the hypothesis that during tubulointerstitial fibrosis α-smooth muscle actin-expressing mesenchymal cells might derive from the tubular epithelium via epithelial-mesenchymal transition under the influence of TGF-β.[185] Strategies to block the process of epithelial-mesenchymal transition are being explored for future therapeutic targets in CKD.[465]

Diagnosis and Screening for Kidney Disease

The patient with kidney disease generally presents to the clinician because of (1) an abnormality detected on a routine biochemical blood screen or urinalysis, (2) a symptom or physical sign, or (3) the patient has a systemic disease with a known renal involvement, such as diabetes mellitus. Effective management of the patient with kidney disease is dependent upon establishing a definitive diagnosis. Initial management includes a detailed clinical history, clinical examination, and assessment of the urinary sediment. Dipstick urinalysis allows for detection of multiple abnormalities simultaneously: clinically proteinuria and hematuria are the most important of these in suspected kidney disease. If blood cells are confirmed on repeat testing and are not associated with urine infection, then the patient should be assessed for kidney or urothelial disease. Cells may originate from the kidneys or from elsewhere in the urinary tract, including the external genitalia. Detection of urinary casts can also be performed by urine microscopy and strongly supports intrinsic renal disease. Detection of proteinuria has been discussed above. Biochemical measurements play an important role in the discovery that kidney damage has occurred and in monitoring progress and treatment. Noninvasive imaging using ultrasonography is invaluable at identifying the size and shape of the kidneys along with any evidence of obstruction. However, percutaneous kidney biopsy is routinely performed to confirm the diagnosis, guide treatment, and gain information regarding prognosis.

Classification of Kidney Failure

The terminology associated with kidney diseases has been amended and is clarified here. Previously, renal failure was divided into either *acute renal failure* (ARF) or *chronic renal failure* (CRF).[216] These terms indicate the rate at which damage occurs rather than the mechanism by which it occurs. Landmark guidelines developed in the USA by the National Kidney Foundation-Kidney Disease Outcomes Quality Initiative (NKF-K/DOQI)[295] attempt to evaluate, classify, and stratify CKD (see Table 45-6). The term "renal" has largely been replaced by "kidney" when referring to *chronic* disease since it is better understood by patients and nonspecialists. However, "acute renal failure" (ARF) remains standard nomenclature along with ESRD.

ARF is diagnosed when excretory function of the kidneys declines over hours or days. ARF is a common condition complicating 5% of hospital admissions.[172] The incidence of ARF increases with age and co-morbidity. One of the problems in identifying the true incidence and outcome of ARF is the spectrum of definitions in published studies ranging from severe (requiring dialysis) to modest increases in plasma creatinine concentrations.[172,239] In 2003, a new

classification of ARF was proposed that was based on the combination of susceptibility, nature and timing of insult, biomarker response, urine output, and end-organ consequences.[278] A prospective study of the initial hospital management of ARF confirmed that in almost 40% of cases ARF was iatrogenic or preventable.[403] Intrinsic ARF can be caused by primary vascular, glomerular, or interstitial disorders. However, in the majority of cases the kidney lesion seen on histology is referred to as acute tubular necrosis (ATN). ATN is caused by ischemic or nephrotoxic injury to the kidney. In 50% of cases of hospital-acquired ARF, the cause is multifactorial. (The term "ATN" is somewhat misleading insofar as necrosis per se is seldom seen, rather tubular *damage.*)

ARF develops rapidly, and therefore its sequelae are mainly a consequence of rapid electrolyte, acid-base, and fluid imbalances that can be difficult to control. The clinical assessment of ARF should consider whether the precipitant is prerenal, intrarenal, or postrenal. The most common causes are listed in Table 45-7. ARF can arise from a variety of pathological conditions, including glomerulonephritis, interstitial nephritis,[407] and arterial, venous, or urinary tract obstruction. As indicated earlier, the most common hospital-based cause is ATN, usually as a result of severe hemodynamic disturbance or exposure to nephrotoxins. Although the pathogenesis is uncertain, there is a well-recognized clinical pattern, with anuria or oliguria and abnormalities indicating tubular dysfunction (Figure 45-11).[38] Necrosis of tubular cells need not be extensive, but there may be obstruction by tubular casts, back-leak of glomerular filtrate through gaps in the tubular epithelium caused by cellular denudation, and primary reductions in GFR caused by altered intrarenal hemodynamics, known as tubuloglomerular feedback.[232] Direct vasoconstriction of glomerular capillaries in response to ischemic insults can also occur and may be mediated by AII, endothelin,[125,451] and serotonin.[433] If the patient survives, recovery will usually occur within days or weeks following removal of the initiating event. Uncomplicated ARF has a mortality rate of 5% to 10%,[172] although ARF complicating nonrenal organ system failure in the intensive care setting is associated with mortality rates approaching 50% to 70% despite advances in dialysis treatment.[278]

The role of the clinical laboratory in the assessment and monitoring of ARF is limited to assessment of electrolyte disturbance and fluid status, as during the recovery period there is an initial polyuric phase as glomerular function recovers before tubular function recovers. This polyuric phase recedes after a few days to weeks but requires careful monitoring to enable suitable fluid and electrolyte replacement.

TABLE 45-6 Stages of Chronic Kidney Disease: Metabolic and Management Consequences

Stage	Description	GFR (mL/min/1.73 m^2)	Metabolic Consequences	Management
1	Kidney damage with normal or increased GFR	>90		Diagnosis and treatment; treatment of comorbid conditions Slowing progression CVD risk reduction
2	Mildly decreased GFR	60-89	Concentration of parathyroid hormone starts to rise (GFR 60-80)	Estimating progression
3	Moderately decreased GFR	30-59	Decrease in calcium absorption (GFR < 50); lipoprotein activity falls Malnutrition Onset of left ventricular hypertrophy Onset of anemia (erythropoietin deficiency)	Evaluating and treating complications
4	Severely reduced GFR	15-29	Triglyceride concentrations start to rise Hyperphosphatemia Metabolic acidosis Tendency to hyperkalemia	Preparation for RRT, if appropriate
5	Kidney failure	<15	Uremia/azotemia	RRT, if appropriate

Modified from National Kidney Foundation Document. Clinical practice guidelines for chronic kidney disease: evaluation, classification, and stratification. Kidney Disease Outcome Quality Initiative. Am J Kidney Dis 2002;39:S1-246.

TABLE 45-7 Causes of Acute Renal Failure

Cause	Agents
Prerenal	
Hypovolemia	Trauma, burns, surgery
Decreased effective plasma volume	Nephrotic syndrome, sepsis, shock
Decreased cardiac output	Congestive cardiac failure, pulmonary embolism
Renovascular obstruction	Atherosclerosis, stenoses
Interference with renal autoregulation	ACE inhibitors, cyclosporine
Renal	
Glomerular and small vessel disease	Aggressive glomerulonephritis (e.g., poststreptococcal, preeclampsia)
Interstitial nephritis	Infection, infiltration, drugs/toxins
Tubular lesions	Postischemic, nephrotoxins, rhabdomyolysis, Bence Jones protein, hypercalcemia
Postrenal	
Bladder outflow obstruction	Prostatism, neurogenic bladder
Ureteric obstruction	Stones, blood clots, tumors, radiotherapy, retroperitoneal fibrosis

DISEASES OF THE KIDNEY

Diseases of the kidney that are discussed in this section include (1) the uremic syndrome, (2) chronic kidney disease, (3) end-stage renal disease, (4) diabetic nephropathy, (5) hypertensive nephropathy, (6) glomerular diseases, (7) interstitial nephritis, (8) polycystic kidney disease, (9) polycystic kidney disease, (10) toxic nephropathy, (11) obstructive uropathy, (12) tubular diseases, (13) renal calculi, and (14) cystinuria. In addition, this section also includes discussions on (1) prostaglandins and NSAIDS in kidney disease, (2) monoclonal light chains and kidney disease, and (3) urinary osmolality.

THE UREMIC SYNDROME

Uremia is defined as the excess within the blood of urea, creatinine, and other nitrogenous end products of amino acid and protein metabolism that are normally excreted in the urine; it is more correctly referred to as *azotemia.*[93] The *uremic syndrome,* the terminal clinical manifestation of kidney failure, is the group of symptoms, physical signs, and abnormal findings on diagnostic studies that results from the failure of the kidneys to maintain adequate excretory, regulatory, and endocrine function. For more than 200 years, scientists have been studying the nature of uremia, but no single retained molecule has yet qualified for the title "uremic toxin," and many now agree that a variety of compounds are potential uremic toxins (Table 45-8). At least

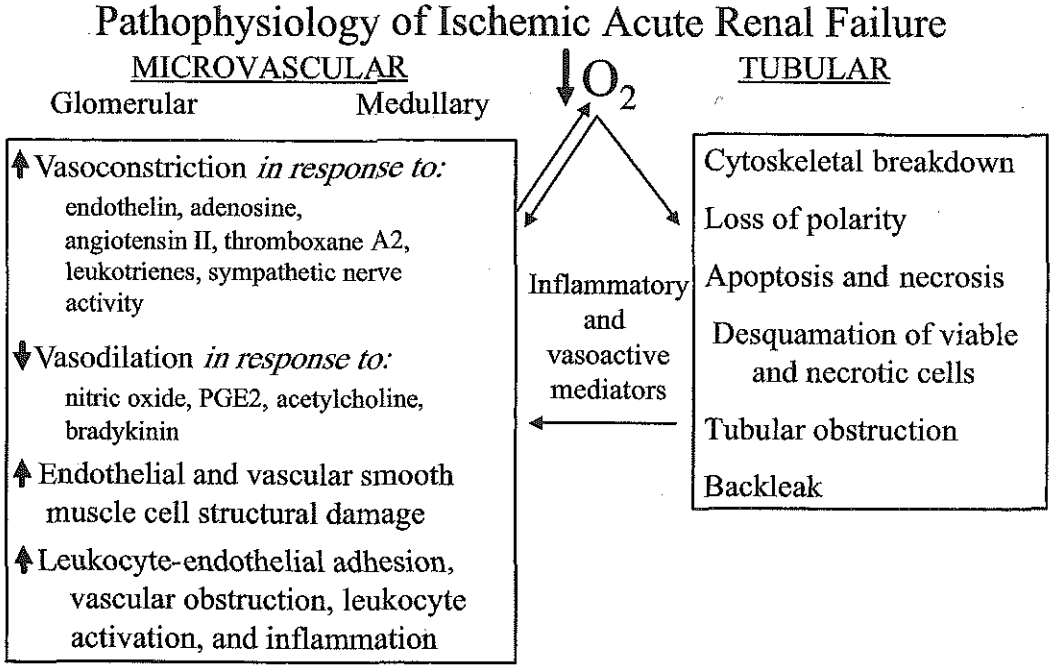

Figure 45-11 Pathogenesis of ischemic acute renal failure. Hypoxic insults cause vascular responses and tubular damage. *(From Bonventre JV, Weinberg JM. Recent advances in the pathophysiology of ischemic acute renal failure. J Am Soc Nephrol 2003;14:2199-210.)*

90 organic compounds have been retained in uremia.[11,430] Many more still unidentified solutes are possibly retained and might exert toxicity.

The classic signs of uremia include progressive weakness and easy fatigue, loss of appetite followed by nausea and vomiting, muscle wasting, tremors, abnormal mental function, frequent but shallow respirations, and metabolic acidosis. The syndrome evolves to produce stupor, coma, and ultimately death unless support is provided by dialysis or successful kidney transplantation.[341] Regulation of body fluids is impaired in patients with uremia because of failure to excrete excess ingested fluid or to cope with fluid losses caused by vomiting or diarrhea. Patients also have difficulty excreting a salt load or retaining sodium when intake is low or vascular volume inadequate. Acid excretion is impaired, as is the ability to excrete nitrogenous metabolites from dietary sources. Consequently the composition of plasma is abnormally labile in response to such factors as diet, state of hydration, gastrointestinal bleeding, vomiting, diarrhea, and intake of therapeutic drugs. In relation to the stages of kidney disease defined by NKF-K/DOQI, kidney failure is present at a level of GFR less than or equal to 15 mL/min/m^2 (Stage 5).[295] At this level there are generally signs and symptoms of uremia, or a need for renal replacement therapy (RRT).

The most characteristic laboratory findings are increased concentrations of nitrogenous compounds in plasma, such as urea nitrogen and creatinine,[325] as a result of reduced GFR and decreased tubular function. Retention of these compounds and of metabolic acids is followed by progressive hyperphosphatemia, hypocalcemia, and potentially dangerous hyperkalemia. Although most patients eventually become acidemic, respiratory compensation by elimination of carbon dioxide is extremely important. In addition, reduced endocrine function is manifested by inadequate synthesis of EPO and calcitriol, with resulting anemia and osteomalacia. Disordered regulation of blood pressure generally leads to hypertension. Biochemical characteristics of the uremic syndrome are summarized in Box 45-1.

In addition to the consequences of reduced excretory, regulatory, and endocrine function of the kidneys, the uremic syndrome has several systemic manifestations—among them pericarditis, pleuritis, disordered platelet and granulocyte function, and encephalopathy—that have been difficult to explain.

Many retained metabolites have been implicated in the systemic toxicity of the uremic syndrome. Although urea was the first of these metabolites to be identified as being increased in uremia, it does not appear to be responsible for the systemic manifestations of uremia. Urea is a 60 Da water-soluble compound that has the highest concentration of presently known uremic retention solutes in uremic plasma. Although its removal by dialysis is directly related to patient survival, the effects of urea on biological systems are not clear. Urea removal by dialysis is not necessarily representative of other molecules retained in the uremic syndrome, particularly protein bound solutes or middle molecules, such as parathyroid hormone and cystatin C.[297] Urea may be the origin of other more toxic moieties. Cyanate, produced endogenously from urea, may produce toxic effects by irreversible carbamylation of proteins.[431] Guanidine compounds, especially methylguanidine, have been implicated in toxicity of experimental renal failure, but their significance in human uremia remains to be proved. Unidentified compounds with molecular weights between 300 and 1500 Da may have a role in the pathogenesis of the clinical syndrome of uremia. However, it is more likely that the syndrome is a result of the cumulative effect of many retained compounds, which may act as toxins and may also have an effect on metabolism in general, for example through enzyme inhibition or derangement in membrane transport. The decreased ability of the kidneys to degrade or eliminate hormones may also have a role.

TABLE 45-8 Potential Uremic Toxins

Toxin	Effect
Urea	At very high concentrations (>300 mg/dL) can cause headache, vomiting, and fatigue, carbamylation of proteins
Creatinine	Possibly affects glucose tolerance and erythrocyte survival
Uric acid	Causes uremic pericarditis
Cyanate	Causes drowsiness, hyperglycemia; a breakdown product of urea, it can cause carbamylation of proteins, altering protein function
Polyols (e.g., myoinositol)	Can cause peripheral neuropathy
Phenols	Can be highly toxic as they are lipid soluble and therefore can cross cell membranes easily
Middle molecules (e.g., atrial natriuretic peptide, cystatin C, delta sleep inducing protein, IL-6, TNF-α, PTH)	CAPD patients show fewer signs of neuropathy than hemodialysis patients (many candidate molecules but none paramount)
β_2-Microglobulin	Causative agent in renal amyloid

CAPD, Continuous ambulatory peritoneal dialysis; *IL-6,* interleukin 6; *TNF-α,* tumor necrosis factor alpha; *PTH,* parathyroid hormone.

Chronic Kidney Disease

Studies established to identify the incidence, causes, and complications of CKD have largely focused on advanced disease and kidney failure. Data obtained from epidemiological surveys have been compromised by the lack of consistent surrogate markers of kidney function to identify established disease. For example, plasma creatinine, calculated creatinine clearance, and measured creatinine clearance have variously been used. The NKF-K/DOQI has published a definition of CKD in an effort to identify its early stages.[295] Early identification is essential so that adverse outcomes of CKD can be prevented or treated. CKD is defined therefore as "either kidney damage or GFR <60 mL/min/1.73 m^2 for at least 3 months." Kidney damage is defined as "pathologic abnormalities or markers of damage, including abnormalities in blood or urine tests or imaging studies."

The NKF-K/DOQI guidelines stratify CKD from stage 1 at the mild end of the spectrum to stage 5, kidney failure or GFR less than 15 mL/min/m^2. Although the cut-off levels between the stages are arbitrary, the process may allow for consistency in prevalence reporting for epidemiological studies and also focused treatment schedules for individual patients (see Table 45-6).

The incidence and major causes of CKD in the United States, United Kingdom, and Australasia have previously been identified from community-based studies and registry databases, such as the United States Renal Data System (USRDS), the United Kingdom Renal Registry Report, and the Australia and New Zealand Dialysis and Transplant Registry (ANZDATA). Similar databases are operated throughout the world. As indicated, the registry databases tend to highlight those patients that develop advanced CKD or ESRD requiring treatment with either dialysis or transplantation. The incidence of less advanced stages of CKD and those patients with ESRD that are not accepted for RRT is less clear. The prevalence of advanced CKD in the United Kingdom in the early 1990s was 132 per million population (pmp) as defined by a plasma creatinine concentration greater than 5.7 mg/dL (500 μmol/L).[212] The same study estimated that 450 pmp have a plasma creatinine greater than 3.4 mg/dL (300 μmol/L). The prevalence patterns vary around the world because of differences in (1) ethnicity, (2) incidence of diabetes and hypertension, and (3) attitudes of physicians to accept patients for treatment. The annual acceptance rate for RRT is increasing worldwide. The annual acceptance rate in the United States is 317 pmp (744 pmp in blacks)[427] and in the United Kingdom is 93 pmp.[425] The age of patients accepted for RRT is increasing, with the majority of new patients undergoing RRT within the age range of 66 to 74 years.[425]

The main causes of CKD leading to kidney failure from 1990 to 2000 in the United States are indicated in Figure 45-12. As indicated, diabetes mellitus is the largest single cause of advanced CKD and accounts for almost 45% of new dialysis patients in the United States. It is particularly prevalent among black Americans. Hypertension is the underlying diagnosis in around 25% of new dialysis patients and is also particularly prevalent among black Americans. The myriad of kidney diseases including glomerulonephritis, infections, hereditary, systemic, interstitial, obstructive, and unknown etiology account for the remainder. In the United Kingdom diabetic nephropathy as a cause of kidney failure is seen in 18% of new patients and is not increasing.[425]

Developing kidney failure is most commonly *monitored* by changes in plasma creatinine concentration and calculated estimation of GFR (see Chapter 24).[64] Obtaining a *diagnosis* relies on screening methods outlined above, and if

BOX 45-1 Biochemical Characteristics of the Uremic Syndrome

Retained Nitrogenous Metabolites
- Urea
- Cyanate
- Creatinine
- Guanidine compounds
- "Middle molecules"
- Uric acid

Fluid, Acid-Base, and Electrolyte Disturbances
- Fixed urine osmolality
- Metabolic acidosis (decreased blood pH, bicarbonate)
- Hyponatremia or hypernatremia
- Hypokalemia or hyperkalemia
- Hyperchloremia
- Hypocalcemia
- Hyperphosphatemia
- Hypermagnesemia

Carbohydrate Intolerance
- Insulin resistance (hypoglycemia may also occur)
  - Plasma insulin normal or increased
  - Delayed response to carbohydrate loading
  - Hyperglucagonemia

Abnormal Lipid Metabolism
- Hypertriglyceridemia
- Decreased high-density lipoprotein cholesterol
- Hyperlipoproteinemia

Altered Endocrine Function
- Secondary hyperparathyroidism
- Osteomalacia (secondary to abnormal vitamin D metabolism)
- Hyperreninemia and hyperaldosteronism
- Hyporeninemia
- Hypoaldosteronism
- Decreased erythropoietin production
- Altered thyroxine metabolism
- Gonadal dysfunction (increased prolactin and luteinizing hormone, decreased testosterone)

the kidney size is well maintained (>8 to 9 cm), a percutaneous renal biopsy can be obtained. This is examined using light and electron microscopy in association with immunohistochemistry and molecular biology techniques.

Establishing the differential diagnosis is important in predicting the rate of decline in kidney function and the selection of the most appropriate treatment. In some cases of aggressive glomerulonephritis, kidney failure develops over a few days or weeks, and at the other extreme diabetic nephropathy can take 10 to 15 years to reach the end stage as highlighted below. Every effort should be made to avoid an acute decline in GFR by minimizing exposure to volume depletion, intravenous radiographic contrast, selected antibacterial agents, NSAIDS and cyclo-oxygenase type 2 (COX-2) inhibitors, and urinary tract obstruction.

Management of CKD

The GFR cutoff values in the NKF-K/DOQI guidelines have been selected on limited data with respect to the relationship between complications and level of GFR. Further studies may refine these values. Nevertheless there is often a causal relationship between the burden of illness and the severity of CKD (see Table 45-6).

Rate of progression of CKD, irrespective of underlying cause, is dependent on both non-modifiable factors, such as age, sex, race, are level of kidney function at diagnosis, and modifiable characteristics, including proteinuria, blood pressure control, and smoking. The progression and treatment options for diabetic nephropathy are discussed separately below. The current discussion will focus on the optimal treatment of non-diabetic CKD.

Lowering blood pressure and reduction of proteinuria have been shown to ameliorate the progression of CKD. The

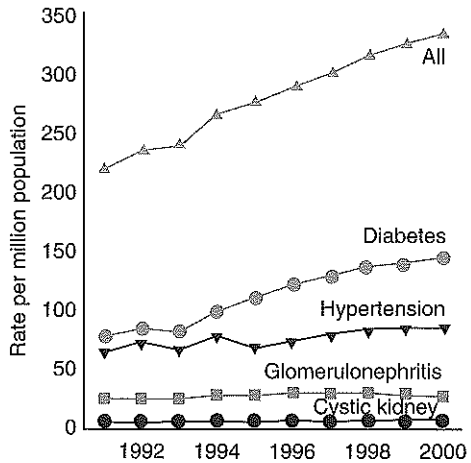

Figure 45-12 Trends in incident rates of end-stage renal disease (ESRD) by primary diagnosis. Diabetes is the primary cause of ESRD in 42% to 47% of adult dialysis patients in the United States. The overall incidence of ESRD has increased by 50% between 1991 and 2000. *(From United States Renal Data System: Excerpts from the USRDS annual data report: atlas of ESRD in the United States. Am J Kidney Dis 2003;(suppl 2) 41:50, with permission from the National Kidney Foundation.)*

Modification of Diet in Renal Disease (MDRD) Study compared the rates of decline in GFR in 840 patients with various causes of CKD to either a "usual" or "low" blood pressure goal.[217] Patients with type 1 diabetes were excluded. Outcome data suggest that the low blood pressure goal had some beneficial effect in those patients with higher levels of proteinuria.[181,217] The study supported the concept that proteinuria is an independent risk factor for progression of kidney disease. For patients with proteinuria of more than 1 g/day, the suggested target for mean blood pressure was 92 mm Hg (125/75 mm Hg).[326] This target for blood pressure is lower than the sixth report of the Joint National Committee on prevention, detection, evaluation, and treatment of high blood pressure (JNC-VI).[392] In 2002, the United Kingdom Renal Association revised the target blood pressure to 130/80 mm Hg for stable CKD and 125/75 mm Hg for progressive CKD.[422] Data from the Third National Health and Nutrition Examination Survey [NHANES III] (1988-1994) revealed that among hypertensive individuals with an elevated plasma creatinine concentration, 75% were on antihypertensive treatment and only 11% had their blood pressure reduced to lower than 130/85 mm Hg.[74]

ACE inhibitors are more effective than other antihypertensive drugs in slowing the rate of progression of proteinuric CKD.[127,268,362] ACE inhibitors cause a mild decrease in GFR (<10 mL/min/1.73 m^2). The development of hypotension, ARF, or severe hyperkalemia (plasma potassium concentration greater than 5.5 mEq/L) should prompt discontinuation of the drug until other causes have been excluded. Short-term studies show that ARBs have effects on blood pressure and proteinuria that are similar to ACE inhibitors. Data from a 2003 study suggest that combining the two classes of drugs can give additional benefit than either drug alone in terms of reduction in proteinuria and progression to primary end-points.[292]

Low-nitrogen (protein) diets have been advocated from the early years of treatment of severe chronic uremia.[126] The very-low-protein diets tested in the MDRD Study were of marginal benefit in these well-supervised patients with very low renal function, but are not well adhered to in practice, may lead to negative nitrogen balance, and are not recommended. Protein intake is restricted spontaneously to approximately 0.6 to 0.8 g/kg/day by uremic patients not receiving dietary advice.[182] To prevent malnutrition, patients receive professional dietary advice, with diets containing an increased proportion of first class protein and increased calorie content of up to 35 kcal/kg/day. The NHANES III has confirmed an association with reduced GFR and malnutrition in noninstitutionalized individuals studied in a cross-sectional survey of more than 5000 participants stratified according to GFR.[124]

General health measures, including cessation of cigarette smoking, should be encouraged. Complications of CKD that develop before the need for RRT are numerous (see Table 45-6) and include cardiovascular disease, bone disease, and anemia.

Cardiovascular Complications of CKD

The incidence of cardiovascular disease is sevenfold to tenfold greater in patients with CKD than in non-CKD age- and sex-matched controls.[447] By the time patients develop the need for RRT there is an approximately 17 times greater risk of cardiovascular death or nonfatal myocardial infarction than age-matched and sex-matched individuals without kidney disease.[10,113] The spectrum of cardiovascular disease studied in CKD includes (1) angina, (2) congestive heart failure, (3) myocardial infarction, (4) peripheral vascular disease, (5) stroke, and (6) transient ischemic attack. Structural heart disease, such as left ventricular hypertrophy (LVH) and valvular heart disease, is a very common sequela to CKD. Up to 75% of patients commencing dialysis have echocardiographic evidence of LVH.[109] The risk factors for cardiovascular disease in CKD are a mixture of the traditional and CKD-specific. Traditional risk factors such as diabetes, hypertension, and dyslipidemia are more likely in CKD patients.[447] In addition there are a number of other risk factors that are CKD-related (Table 45-9).

Observational studies have indicated that cardiovascular disease occurs at an early stage in CKD.[438] Thus among middle-aged men, a moderate increase in plasma creatinine concentration [>1.5 mg/dL (>130 μmol/L)] was associated with an age-adjusted relative risk of 1.5 for coronary disease and 3.0 for stroke. Reduction of GFR is associated with increased risk of composite end-points of cardiovascular death, myocardial infarction, and stroke.[263] Microalbuminuria and proteinuria have also been shown to be associated with increased risk of cardiovascular disease, cardiovascular mortality, and all-cause mortality.[2,76,437] These associations may arise because (1) CKD causes an elevated level of cardiovascular disease, (2) cardiovascular disease causes CKD, or (3) some other factor, such as diabetes and hypertension, causes both CKD and cardiovascular disease. Significantly, there are 30 times more patients with Stage 3 CKD than Stage 5 CKD.[194,427] The majority die from cardiovascular disease before they progress to kidney failure.

TABLE 45-9 Traditional and CKD-Related Risk Factors for Cardiovascular Disease in CKD

Traditional Risk Factors for Cardiovascular Disease	CKD-Related Risk Factors for Cardiovascular Disease
Older age	Extracellular fluid overload
Male gender	Left ventricular hypertrophy
White race	Proteinuria
Hypertension	Anemia
Elevated LDL cholesterol	Abnormal calcium phosphorus metabolism
Decreased HDL cholesterol	Dyslipidemia
Diabetes mellitus	MIA syndrome
Smoking	Infection
Sedentary lifestyle	Thrombogenic factors
Menopause	Oxidative stress
Family history	Elevated homocysteine
	Uremic toxins

LDL, Low-density lipoprotein; *HDL*, high-density lipoprotein; *CKD*, chronic kidney disease; *MIA*, malnutrition inflammation atherosclerosis.

Left Ventricular Hypertrophy in CKD

LVH is present in more than 70% of patients commencing dialysis.[109] In the dialysis population, LVH is an independent predictor for cardiac death that is the most common cause of death in these patients.[109,113] As indicated above, LVH is demonstrable early in the course of CKD, with the proportion of patients with LVH increasing as kidney function declines. Univariate analysis of a single-center cohort of CKD patients in Canada revealed that age, systolic blood pressure, and hemoglobin were significantly different between the groups with or without LVH.[236] For each 5 mm Hg increase in systolic BP, the risk of LVH increased by 3%. A fall in blood hemoglobin concentration of 1 g/dL increased risk of LVH by 6%. A large, prospective, multicenter study confirmed progressive increases in left ventricular mass index (LVMI) over a 12-month period, with the incidence of new LVH at 10% per year.[237] Again, lower hemoglobin levels and higher systolic blood pressures were associated with left ventricular growth. Normalizing hemoglobin concentration is possible and may have cardiovascular benefits (see discussion later in this chapter).

Anemia

The World Health Organization defines anemia as a hemoglobin of less than 13 g/dL in men and less than 12 g/dL in women.[458] It is clearly established that anemia is inevitable as CKD progresses. Therapies are available to correct anemia and therefore it is mandatory to assess a patient with CKD for anemia. The NKF-K/DOQI recommends that an estimated GFR of less than 60 mL/min/1.73 m^2 should be the cutoff value for determining presence or absence of anemia.[293] Detection is important since, left untreated, it causes many of the side effects of CKD, such as fatigue, breathlessness on exertion, intolerance to cold, and decreased exercise capacity. As indicated above, it is also a major factor in the high prevalence of cardiovascular disease in patients with CKD.

Etiology

The etiology of anemia in CKD is multifactorial. A major cause, however, is the loss of peritubular fibroblasts within the renal cortex that synthesize EPO. EPO is the glycoprotein hormone responsible for stimulating erythroid progenitor cells within the bone marrow to produce red blood cells. Failure of production leads to inappropriately low

concentrations within the blood for the concomitant level of hemoglobin. Other causes of anemia include absolute or functional iron deficiency, folic acid and vitamin B_{12} deficiencies, and chronic inflammation. Red cell survival may also be reduced. Both the NKF-K/DOQI and the European Renal Association-European Dialysis Transplant Association have published algorithms for treatment of anemia in CKD and dialysis patients.[101] Treatment in Europe is targeted to achieve a hemoglobin level of 11 to 13 g/dL.

Assessment of Iron

In patients with CKD, a plasma ferritin <100 μg/L is considered to suggest iron deficiency, and a plasma ferritin of 100 to 200 μg/L in association with a transferrin saturation (TSAT) of <20% represents "functional" iron deficiency. Treatment of anemia in CKD requires adequate iron stores. Parenteral iron is the treatment of choice for absolute and functional iron deficiency since oral iron has low efficacy in CKD. Iron status is assessed by measurement of plasma ferritin and TSAT. The TSAT is calculated from the plasma iron divided by the total iron binding capacity (TIBC) and expressed as a percentage. TSAT gives an indication of iron "delivery." Ferritin is used to represent iron stores. A very high concentration of ferritin (>800 μg/L) may suggest iron overload (see Chapter 31). However, limitations with these indices exist (e.g., a high ferritin concentration is also generated by an inflammatory process and transferrin varies with nutritional state and is also influenced by inflammation). Clinical hematology laboratories may offer an automated estimate of the percentage of hypochromic red blood cells. A level above 10% is indicative of functional iron deficiency and the target is <2.5%.[101]

Treatment

Human recombinant erythropoietin (rhEPO or epoetin) is is a synthetic version of human EPO that is used to treat anemia. Following replenished iron stores and exclusion of other causes of anemia, the addition of recombinant epoetin is indicated for the treatment of CKD-related anemia. The gene for human EPO was cloned in 1985 and epoetin was introduced into clinical practice shortly afterwards.[186,455] It is effective at correcting the anemia of CKD in 90% to 95% of patients. The most common side effect is hypertension and therefore blood pressure should be well controlled before the introduction of treatment. Hypertension may develop or worsen in 23% of patients. Failure to respond to treatment requires thorough investigation for many potential causes (Box 45-2). It is estimated that 3 million patients worldwide have received treatment with epoetin. Pure red cell aplasia (PRCA) has occurred in patients treated with epoetin. This has been described in a small number of patients receiving epoetin via the subcutaneous route. In the majority of cases, neutralizing antibodies to EPO have been detected.[61] If a case of PRCA is proven, then no further recombinant erythropoietin products can be administered.

BOX 45-2 Failure to Respond to Epoetin

Iron status
Occult blood loss
Vitamin B_{12} or folate deficiency
Infection and inflammation
Inadequate dialysis
Hyperparathyroidism
Aluminum toxicity
Patient adherence
Hypothyroidism
Primary disease activity
Transplant rejection
Malignancy
Pure red cell aplasia

There are many clinical benefits of correcting anemia with epoetin therapy, including improved exercise capacity,[274] improved cognitive function,[266] better quality of life,[286,352] and increased libido. Much of the evidence derives from studies in dialysis patients. In patients with advanced CKD not yet on RRT, small nonrandomized studies have suggested that regression of LVH is possible with partial correction of anemia with epoetin.[156,334] Patients who receive epoetin consistently in the 2 years before commencement of dialysis have improved survival on dialysis compared with those who received the least consistent administration.[462] Clinical trials are ongoing to try to answer the key question of whether early normalization of anemia in CKD will translate into improved cardiovascular outcomes.

Dyslipidemia in CKD

Various dyslipidemias are associated with CKD.[270,345,447] The pattern of dyslipidemia in CKD differs from that seen in non-CKD. It is characterized by an accumulation of partly metabolized triglyceride-rich particles [predominantly very-low-density lipoprotein (VLDL) and intermediate-density lipoprotein (IDL) remnants], mainly due to abnormal lipase function.[304] This causes hypertriglyceridemia and low high-density lipoprotein (HDL) cholesterol. Although total cholesterol concentration may be normal, there is often a highly abnormal lipid subfraction profile with a predominance of atherogenic small, dense LDL particles.[10] Lipoprotein a levels are also increased in CKD. Baseline data from the Chronic Renal Impairment in Birmingham (CRIB) study have confirmed dyslipidemia in early CKD.[447] Patients had lower HDL and LDL cholesterol and higher triglyceride concentrations.

The challenge to the nephrology community is to establish whether interventions to modify the pattern of dyslipidemia with lifestyle changes and drug treatment will preserve kidney function and reduce cardiovascular morbidity and mortality. At present, there are no large, adequately controlled trials testing the hypotheses that treatment of

dyslipidemia preserves kidney function. The major trials of intervention with statins [3-hydroxy-3-methylglutaryl-Co-enzyme A (HMG-CoA) reductase inhibitors] in the general population and those with established cardiovascular disease have been limited with reference to CKD, since patients with CKD are often excluded from the trials.[249,330,372] The Heart Protection Study randomly allocated 20,536 adults with coronary artery disease, occlusive disease of noncoronary arteries, or diabetes to simvastatin (40 mg) or placebo.[277] In a subgroup analysis of more than 1300 patients with plasma creatinine concentration between 1.2 mg/dL and 2.3 mg/dL (110 and 200 μmol/L), there were fewer major vascular events in the simvastatin group.

A randomized controlled trial of proteinuric CKD patients receiving ACE inhibitors and ARBs demonstrated additional benefit from treatment with atorvastatin in terms of reduction in proteinuria and progression of disease.[26] Further trials of lipid-lowering therapies in CKD are currently underway.

Homocysteine

Homocysteine is a sulfur-containing amino acid (see Chapters 20, 26 and 40). Homozygous genetic disorders (homocystinurias) result in marked hyperhomocysteinemia and are clearly associated with untimely atherothrombotic events.[288] Treatment to lower homocysteine reduces the incidence of such outcomes among these patients. Patients with CKD have an excess prevalence of mild-to-moderate hyperhomocysteinemia, which has been independently linked to the development of cardiovascular disease in observational studies.[43] In case-control studies, plasma homocysteine levels are frequently higher in patients with clinical evidence of vascular disease than those without, both in the general population and in CKD.[44] Folate, pyridoxal 5′-phosphate (PLP or "active" vitamin B_6), and vitamin B_{12} are the main vitamin cofactors and/or substrates for homocysteine metabolism (see Chapter 30). Folic acid–based B vitamin regimens, including folic acid at doses of 5 to 10 mg/day, appear to lower fasting homocysteine levels by approximately 30% to 50%.[42] There is as yet little evidence that intervention to lower homocysteine levels affects the risk of disease in the general population or in CKD patients. However, correction of folate deficiency is considered good clinical practice.

Role of Nephrologist

The role of the nephrologist in CKD is to (1) identify the cause of kidney disease, (2) treat reversible factors, (3) reduce rate of progression of CKD, and (4) deal with complications of CKD. Finally, as kidney function fails, the patient should enter an RRT program in a good general condition with suitable access for dialysis, educated and psychosocially prepared for ongoing treatment.

End-Stage Renal Disease

ESRD is an administrative term in the United States, based on the conditions for payment for healthcare by the Medicare ESRD Program, specifically the level of GFR and the occurrence of signs and symptoms of kidney failure necessitating initiation of treatment by RRT. ESRD includes patients treated by dialysis or transplantation, irrespective of the level of GFR (see later section on RRT and transplantation). The NKF-K/DOQI definition of kidney failure (stage 5) differs in two important ways from the definition of ESRD. First, not all individuals with GFR <15 mL/min/1.73 m^2 or with signs and symptoms of kidney failure are treated with RRT. However, such individuals should be considered as having kidney failure. Second, among treated patients, kidney transplant recipients have a higher mean level of GFR (usually 30 to 60 mL/min/1.73 m^2) and better average health outcomes than dialysis patients. Kidney transplant recipients should not be included in the definition of kidney failure, unless they have GFR <15 mL/min/1.73 m^2 or have resumed dialysis.

Kidney diseases or conditions that can lead to ESRD include LVH, anemia, dyslipidemias, disturbed calcium and phosphorus metabolism, and aluminum toxicity.

LVH and Anemia

In a prospective study of ESRD at three Canadian centers, of the 518 patients who survived 6 months of dialysis, 74% had echocardiographic confirmation of LVH.[109] Thirty-five percent had left ventricular dilation (LV cavity >90 ml/m^2) and 15% had systolic dysfunction (fractional shortening of less than or equal to 25%). LVH and dilation were independently associated with death at 2 years.

Anemia has both direct and indirect effects on left ventricular function and growth. Cardiac output increases because of a combination of increased cardiac preload and a reduction in afterload. Such changes lead to ventricular remodeling, with initial left ventricular dilation followed by subsequent hypertrophy. In ESRD other factors also contribute to LVH, including hypertension, volume expansion, and the metabolic consequences of uremia, to which may be added the effects of diabetes. By the time patients with diabetes reach ESRD, they are more likely to have concentric LVH, more likely to have had ischemic heart disease, and more likely to have experienced cardiac failure than nondiabetic subjects.[112]

Predictors for LVH and cardiac failure include age, hypertension, and hemoglobin concentration. In ESRD a 1 g/dL fall in hemoglobin increases the relative risk of left ventricular dilation by 1.49, left ventricular systolic dysfunction by 1.55, and death by 1.25.[110] In patients on dialysis, large observational studies have clearly shown that anemia is associated with increased mortality rates and increased hospitalization.[72,248,253,461] In hemodialysis (HD) patients hematocrit levels of 33% to 36% (corresponding to hemoglobin concentration of 11 to 12 g/dL) were associated with the lowest risk for all-cause and cardiac mortality,[253] and these patients also had the lowest risk of hospitalization.[305,461] A large randomized controlled trial has tested the hypothesis that normalization of anemia would have benefits in terms of

morbidity and mortality for hemodialysis patients with New York Heart Association (NYHA) heart disease stage I-III.[24] Patients were randomized to normalization of anemia (618 patients and target hemoglobin of 14 g/dL), or to the control group (615 patients and target hemoglobin of 10 g/dL). The study was terminated early because of a nonsignificant higher risk of death in the normalization group (RR = 1.3, CI 0.09 to 1.9). Post hoc analysis revealed that although the *target* hemoglobin levels in the two groups were clearly separated, the *achieved* hemoglobin levels in the two groups were not and mortality was actually lowest in the subset of patients with the highest achieved hemoglobin level (>13 g/dL).

Dyslipidemias

The prevalence of dyslipidemias in ESRD is high. Dyslipidemias in HD patients are most often characterized by normal LDL, low HDL, and high triglycerides. In a large cross-section analysis of 1047 HD patients in the Dialysis Morbidity and Mortality Study, only 20% of patients had low risk lipid levels [i.e., LDL <130 mg/dL (3.36 mmol/L), HDL >40 mg/dL (>1.03 mmol/L), and triglycerides <150 mg/dL (<1.69 mmol/L)].[296] Low cholesterol was found to be associated with increased mortality, but this is probably a reflection of other conditions that lower cholesterol, such as inflammation and malnutrition. It is possible that other, nontraditional atherogenic lipoprotein abnormalities (e.g., lipoprotein [a] and oxidized LDL) are present in HD patients.[117,257] Similar profiles may be observed in peritoneal dialysis (PD) patients. Treatment guidelines aim to reduce LDL and triglycerides to normal levels. As indicated in the discussion of dyslipidemias in CKD, many of the data on treatment with HMG Co-A reductase inhibitors have been obtained in largely non-CKD populations.

Disturbances in Calcium and Phosphorus Metabolism

ESRD is associated with complex metabolic disturbances of divalent ion and phosphorus metabolism. Although this is commonly referred to as *renal osteodystrophy*, there has been a paradigm shift in terms of calcium, phosphate, and PTH management in patients receiving dialysis. The impetus for this change in approach has been the recognition of the importance in the previously unheralded phosphorus moiety in terms of increased risk of death in ESRD and the almost universal development of *cardiovascular calcification* that is seen in dialysis patients (discussed later in this chapter). As GFR declines, plasma phosphate concentration rises and results in a reduction in ionized calcium. The consequence of this is increased production of PTH from the parathyroid glands. The PTH-producing cells are regulated tightly through complex feedback mechanisms to maintain normocalcemia (see Chapter 49). The calcium-sensing receptor (Ca-SR) is stimulated by calcium and has an inhibitory effect on PTH production.[49] Phosphorus will directly stimulate production of PTH.[395] Elegant experiments on dogs with varying levels of induced kidney failure

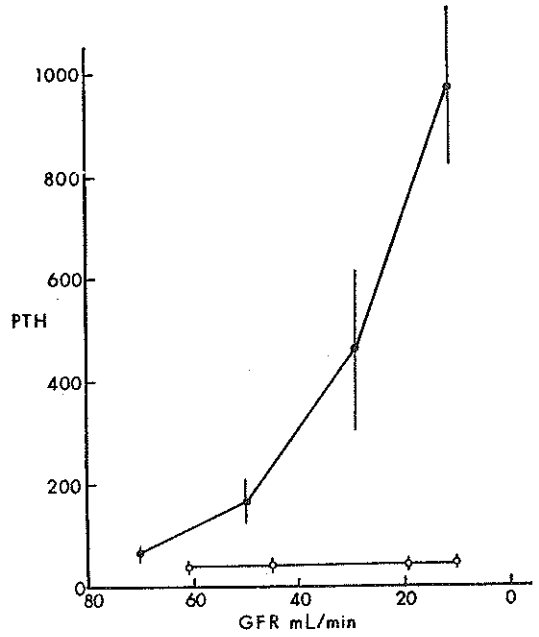

Figure 45-13 The relationship between parathyroid hormone (PTH) concentration and glomerular filtration rate (GFR) in two groups of dogs: those maintained on a normal phosphorus diet (closed circles) and those maintained on a diet containing less than 100 mg of phosphorus per day (open circles). The vertical lines represent ±1 SEM. PTH is expressed in μEq/mL. *(From Slatopolsky E, Caglar S, Pennell JP, Taggart DD, Canterbury JM, Reiss E, et al. On the pathogenesis of hyperparathyroidism in chronic experimental renal insufficiency in the dog. J Clin Invest 1971;50:492-9.)*

confirmed the rise in PTH as GFR falls. This increased production of PTH was attenuated in those animals fed a modified diet with very low levels of phosphorus[394] (Figure 45-13). In addition to hyperphosphatemia contributing to hypocalcemia, there is also reduced 1α-hydroxylation of 25-hydroxycholecalciferol (25-OH vitamin D) within the kidney. Vitamin D is required in health to increase calcium absorption from the gut and it also increases phosphorus absorption from the gut. PTH-producing cells in the parathyroid gland have receptors for vitamin D (VDR). Binding of vitamin D to the VDR inhibits PTH production. The result of these complex metabolic disturbances is secondary hyperparathyroidism. Increased secretion of PTH stimulates resorption of calcium and phosphorus from the major calcium reservoir, the bone. Problems can develop early and patients with a GFR of less than 60 mL/min/1.73 m^2 should be evaluated for these metabolic disturbances.[295] Secondary hyperparathyroidism classically causes bone changes consistent with osteitis fibrosa cystica. Bony erosions and intramedullary cysts are seen because of direct effects of PTH on osteoclasts and osteoblasts. Unchecked, this can lead to bone pain and fractures. Eventually, PTH secretion can become unhinged completely from feedback control and this autonomous production is called tertiary

hyperparathyroidism. Derangements in biochemical indices include elevated plasma calcium and phosphate concentration, PTH levels more than 1000 ng/L (reference interval 10 to 60 ng/L), and elevated bone-derived alkaline phosphatase. In this setting medical treatment has failed and parathyroidectomy is required. A severe and often terminal manifestation of long-standing ESRD is calcemic uremic arteriolopathy ("calciphylaxis"). In this condition there is destruction of blood vessels because of calcium deposition and downstream necrosis of tissues, particularly the skin and adipose tissue on the legs and torso.

High concentrations of blood phosphorus are associated with increased mortality in HD patients.[31] The relative risk of death in the United States for those HD patients with plasma phosphorus greater than 6.5 mg/dL (2.10 mmol/L) is 1.27 relative to those with plasma phosphorus of 2.4 to 6.5 mg/dL (0.77 to 2.10 mmol/L). The calcium phosphorus product (calculated by multiplying concentration of calcium by concentration of phosphorus) showed a mortality trend similar to phosphorus. In at least 50% of HD patients the plasma phosphate is greater than 6.0 mg/dL (1.94 mmol/L) and in 25% of patients it is greater than 7.2 mg/dL (2.32 mmol/L). The United Kingdom Renal Association standard for pre dialysis plasma phosphate concentration is less than 5.6 mg/dL (1.8 mmol/L).[422] Strategies to reduce phosphorus levels are employed routinely in the treatment of patients on dialysis. Inorganic phosphorus measured within the blood accounts for <0.1% of total body phosphorus. The clearance of phosphorus on intermittent HD is approximately a third of that of urea and is also subject to a post dialysis rebound because of efflux from the intracellular to extracellular space. Phosphorus is present in many foods and is linearly associated with protein ingestion. The recommended daily allowance is reduced for patients on dialysis to around 800 mg. Treatment with vitamin D analogs increases gut absorption of phosphorus from 60% to 70% to almost 85%. The use of phosphate binders, taken with meals, is almost universal in dialysis patients. The binders reduce phosphorus absorption to 30% to 40%. In summary, patients on conventional dialysis are in a net positive phosphorus balance. It has been possible to normalize phosphorus balance in patients treated by daily HD.[287]

Medical treatment strategies are designed to limit phosphorus intake and normalize calcium. With the advent of vitamin D analogs it has been possible to supplement vitamin D (see Chapter 49). This has the effect of increasing plasma calcium concentration and switching off PTH production. Unfortunately the commonly used analogs, such as 1α-hydroxyvitamin D_3, also lead to increased reabsorption of calcium and phosphorus from the gut. Hyperphosphatemia has deleterious cardiovascular effects and is discussed below. Furthermore, in the setting of aggressive treatment with vitamin D analogs hypercalcemia may develop that is associated with low, suppressed, levels of PTH. Bone biopsy in this case may demonstrate very low levels of bone activity, a condition referred to as adynamic bone disease. Alternative vitamin D analogs such as paricalcitol are reported to have lower rates of hyperphosphatemia.[267,409] A further development has been the generation of calcimimetic agents that are currently being evaluated in clinical trials.[6,243] These drugs can mimic calcium directly stimulating the Ca-SR and also affect the molecular configuration of the Ca-SR to enhance the sensitivity to extracellular calcium.[243] Stimulation of the Ca-SR switches off PTH production selectively with no risk of increasing phosphorus absorption.

Aluminum Toxicity

A causative factor for renal bone disease, historically, is aluminum intoxication (see Chapter 35). Aluminum concentrations in dialysis fluids were previously high, but with modern dialysis facilities this is no longer such a problem. Dialysis patients are, however, treated intermittently with aluminum-containing phosphate binders and therefore regular monitoring of blood aluminum concentration is recommended.[422] Aluminum accumulation has been associated with deposition along the mineralization surface of the osteoid and a low-turnover form of bone disease. Aluminum accumulation may be treated by infusions of the chelating agent desferrioxamine. Aluminum intoxication may be associated with neurological disturbances characterized by dementia (dialysis dementia) and with a hypochromic microcytic anemia.

Diabetic Nephropathy

Diabetes mellitus is a state of chronic hyperglycemia sufficient to cause long-term damage to specific tissues, notably the retina, kidney, nerves, and arteries (see Chapter 25). It affects 176 million people worldwide and the World Health Organization (WHO) predicts that the prevalence of diabetes is set to double by 2030.[215,459] In the United Kingdom 3% of the population have diabetes.[421] The WHO and national diabetes agencies have approved diagnostic criteria for diabetes based on venous plasma glucose concentrations.[351]

Type 1 diabetes is due to autoimmune destruction of pancreatic islet beta cells causing loss of insulin. Type 2 diabetes is due to the combination of cellular resistance to insulin and beta cell failure. Tissue lesions are common to both types of diabetes, and chronic hyperglycemia (or a closely related metabolic abnormality) is responsible for diabetic complications including diabetic nephropathy.

Background

Diabetic nephropathy is a clinical diagnosis based on the finding of proteinuria in a patient with diabetes and in whom there is no evidence of urinary tract infection. Overt nephropathy is characterized by protein excretion greater than 0.5 g/day. This is equivalent to albumin excretion of around 300 mg/day. It is preferable to assess proteinuria as albuminuria because it is a more sensitive marker for CKD

due to diabetes.[295] There has been a uniform adoption of albumin as the "criterion standard" in evaluating diabetes-related kidney damage. The NKF-K/DOQI Work Group concluded that albumin should be measured to detect and monitor kidney damage in adults. Patients with a urinary albumin excretion rate of between 30 and 300 mg/day have microalbuminuria (see Chapter 24). Diabetic nephropathy is the most common cause of ESRD in the United States and accounts for approximately 40% of incident patients onto RRT programs.[427] More than 100,000 people receiving HD in the United States have diabetes as the cause of their ESRD. Among patients who require dialysis, those with diabetes have a 22% higher mortality at 1 year and a 15% higher mortality at 5 years than patients without diabetes. Diabetic nephropathy as a cause of ESRD in the United Kingdom is seen in 18% of new patients and remains lower than that of the United States and Europe.[425] In the United States, a number of objectives have been developed for reducing threats to the health of the nation in the Healthy People 2010 report. One of the objectives (HP 2010 Objective 4.7) is to reduce the incidence rate of ESRD caused by diabetes from 145 per million population to 78 per million people by 2010.[427]

Diabetic nephropathy is clinically a very slowly developing condition, but ultrastructural evidence of glomerular damage has been found in renal biopsies taken from type 1 diabetic patients within a few years of their diagnosis.[15,66,104] In type 1 disease, early macroscopic changes include kidney enlargement and pallor. With disease progression, the kidneys become smaller. Type 2 disease is typified by variable kidney contraction because of associated ischemia. On histological examination, glomerular changes include diffuse mesangial sclerosis with accentuation of matrix and irregularly thickened basement membranes; sclerotic, acellular mesangial nodules (so-called Kimmelstiel-Wilson lesions); hyaline fibrin cap lesions around peripheral capillary loops; capsular drop lesions located within Bowman's capsule; and hyalinosis of arterioles.

Clinical progression is defined in terms of changes in urinary albumin excretion rate and decline in GFR and blood pressure (Table 45-10). In type 1 diabetes, it is unusual to develop microalbuminuria within the first 5 years of diagnosis but it can develop anytime thereafter and even after 40 years. Patients with type 1 disease and microalbuminuria will progress to overt nephropathy at an average rate of 20% over 5 years.[114] Long-term follow-up data of microalbuminuric patients confirm that 30% become normoalbuminuric and the rest remain microalbuminuric at 10 years.[58] Since the onset of type 2 diabetes is difficult to define, it is difficult to estimate the incidence of microalbuminuria, although 1% of patients in the United Kingdom have overt nephropathy at diagnosis. As albuminuria worsens and blood pressure increases, there is a relentless decline in GFR. In some patients with microalbuminuria renal lesions are already quite advanced and therefore it may be a marker of nephropathy rather than a predictor of renal structural changes.[58]

Family studies of patients with type 1 diabetes have shown that diabetic siblings of patients with nephropathy have a fourfold risk of nephropathy compared with a sibling without nephropathy. A family history of hypertension and cardiovascular disease may also increase nephropathy rates.[39] However, the best available predictor for development of nephropathy is microalbuminuria, although cellular markers are being investigated—such as increased erythrocyte Na^+/Li^+ countertransporter and overactivity of the Na^+/H^+ antiporter.[17] Considerable work has been undertaken to look for genetic linkages with the development of nephropathy in diabetes. This work has included studies of polymorphisms of the ACE and insulin genes, but as yet no clear relationship has been demonstrated.[376] Other markers of basement membrane damage have also been used to investigate dia-

TABLE 45-10 Development of Diabetic Nephropathy

Stage	Designation	Characteristics	Structural Changes	GFR (mL/min/1.73 m²)	Blood Pressure (mm Hg)
I	Hyperfunction	Hyperfiltration	Glomerular hypertrophy	>150	Normal
II	Normo-albuminuria	Normal AER	Basement membrane thickening	150	Normal
III	Incipient diabetic nephropathy	Elevated AER	AER correlates with structural damage and hypertrophy of remaining glomeruli	125	Increased
IV	Overt diabetic nephropathy	Clinical proteinuria	Advanced structural damage	<100	Hypertension
V	Uremia	End-stage renal disease	Glomerular closure	0-10	High

AER, Albumin excretion rate; *GFR*, glomerular filtration rate.

betic nephropathy, including urinary excretion of laminin, collagen IV, and fibronectin.[187,340]

Pathophysiology

Observational studies have shown that sustained poor glycemic control is associated with a greater risk for development of nephropathy in both type 1 and type 2 diabetes.[89,174-176,218,345,424] The exact mechanism for hyperglycemic tissue damage is now being elucidated and probably includes (1) glycation of proteins leading to the formation of advanced glycation end products (AGE), (2) overactivity of the polyol pathway, and (3) generation of reactive oxygen species. Polyols are sugar alcohols formed from their respective sugars under the action of aldose reductase. Glucose is preferentially shunted through the polyol pathway under hyperglycemic conditions, generating sorbitol that accumulates within cells. A key step linking glucotoxicity to cell dysfunction in diabetic nephropathy is the excess of extracellular matrix within the glomerulus and interstitium. A number of genes encoding matrix proteins in hyperglycemic conditions have been identified.[269] For example, the transcription of the gene for transforming growth factor-β (TGF-β) is stimulated by hyperglycemia, AGE, angiotensin II, and reactive oxygen species.[168,315,443] One important consequence of glucose-stimulated TGF-β is the upregulation of the insulin-independent GLUT-1 transporter in mesangial cells. Glucose is transported to the cells through GLUT-1 and metabolized mainly by the glycolytic pathway. Increased de novo synthesis of diacylglycerol results in the activation of protein kinase C and mitogen activated kinases. Activation of these enzymes can lead to stimulation of certain genes, including TGF-β. Activation of TGF-β can induce the expression of GLUT-1 and these signaling pathways induce expression of extracellular matrix proteins. The formation of AGE also generates reactive oxygen species, which can activate latent TGF-β.[269] Studies employing neutralizing anti–TGF-β antibodies have provided evidence that the prosclerotic and hypertrophic effects of high ambient glucose in cultured renal cells are largely mediated by autocrine production and activation of TGF-β.[184,471] These antibodies can reverse established nephropathy in animal models.[68,472] Furthermore, glomerular TGF-β mRNA is markedly increased in kidney biopsy specimens from patients with proven diabetic kidney disease, and blood and urine sampling across the renal vascular bed confirms net renal production of TGF-β in diabetic patients.[386] Treatment with the ACE inhibitor captopril lowers circulating TGF-β levels in patients with diabetic nephropathy.[387] The receptor for AGE has been identified (RAGE).[375] RAGE is selectively expressed in the glomerular epithelial cells (podocytes) and not the mesangial cell or glomerular endothelium.[406] Increased accumulation of AGE in diabetes engages podocyte RAGE and may lead to increased glomerular permeability.[446] Vascular hyperpermeability, a hallmark feature of diabetes, can be suppressed by inhibiting RAGE in the animal model of diabetes, the streptozotocin-treated rat.[441]

Studies of experimental diabetes in the rat suggested that hyperfiltration alone could cause glomerular changes; there are conflicting reports in humans. An increased GFR could be a predictor of progression to microalbuminuria, but is also a reflection of poor metabolic control. In the Diabetes Control and Complications Trial (DCCT) study, there was no association between hyperfiltration and subsequent development of microalbuminuria.[17] Systemic blood pressure is higher in patients with diabetes who subsequently develop microalbuminuria, although it is not clear which comes first. Tubulointerstitial fibrosis occurs in diabetic nephropathy in addition to glomerulosclerosis. Decreased GFR correlates with the interstitial expansion and the glomerular expansion.[449]

Treatment Strategies

The DCCT found in almost 1500 patients with type 1 diabetes that 9 years of intensive insulin therapy compared with conventional insulin therapy produced a 44% reduction in the development of microalbuminuria in patients with no retinopathy and a 35% reduction in patients with early retinopathy at entry.[89] The cumulative incidence of microalbuminuria was 15% and 27% in the intensively treated patients, respectively. The mean glycated hemoglobin (HbA_{1c}) was 7.2% in the intensively treated group versus 9.0% in the conventionally treated patients.

The United Kingdom Prospective Diabetes Study (UKPDS) of almost 4000 newly diagnosed type 2 diabetic patients followed for at least 10 years, showed that intensive control of blood glucose with sulfonylureas or insulin reduces the risk of diabetic nephropathy and other microvascular complications.[424] The target fasting blood glucose was 110 mg/dL (6.1 mmol/L) for the interventional group and for standard therapy was 270 mg/dL (15 mmol/L). Fasting blood sugars rose over time in both groups but mean HbA_{1c} was lower in the intervention group (7.0% compared with 7.9%). The UKPDS showed additional benefit of intensive therapy, with a 67% risk reduction on the rate of doubling of plasma creatinine at 12 years, although less than 1% of UKPDS patients developed advanced CKD.

Studies from Japan and Scandinavia have reported a lower incidence of microalbuminuria in intensively treated groups of patients with type 2 diabetes.[119,306] The American Diabetes Association Clinical Practice Recommendations target HbA_{1c} to less than 7% as the treatment goal. Additional therapy should be initiated if HbA_{1c} is above 8%.[401]

There is ongoing controversy as to whether intensive glucose therapy alone can prevent progression of incipient to overt nephropathy. Other factors, such as lowering blood pressure and blockade of ACE and AII, are important. High blood pressure accelerates the progressive increase in albuminuria in patients with initially normal urinary albumin excretion and accelerates loss of kidney function in those with overt nephropathy in type 2 diabetes.[12] A subgroup analysis of the Swedish Hypertension Optimal Trial (HOT)

showed that patients with diabetes who were randomized to lower levels of blood pressure (diastolic blood pressure <90 versus <85 versus <80 mm Hg) had lower mortality and cardiovascular events than those with higher values.[150] In 1501 patients with diabetes, a 50% reduction of major cardiovascular events was seen in those targeted to a diastolic blood pressure less than 80 mm Hg as compared with 90 mm Hg. The NKF Task Force on Cardiovascular Disease has recommended a target blood pressure of less than 125/75 mm Hg in diabetic kidney disease.[235] The recent report of aggressive blood pressure control in normotensive type 2 diabetic patients reinforces this target blood pressure as appropriate in diabetes.[378]

Patients with diabetes are relatively more hypervolemic than nondiabetic patients at the same level of GFR. Therefore, it is important to emphasize reduced dietary salt intake and diuretic treatment in the management of diabetic patients with nephropathy. A low sodium diet potentiates the antihypertensive effect and antiproteinuric effect of AII blockade in type 2 diabetes.[173] Patients should be encouraged to stop smoking cigarettes since smoking increases the risk of microalbuminuria.[308] Dyslipidemias should be managed as outlined for nondiabetic proteinuric CKD.

ACE inhibitors and ARBs slow the progression of diabetic kidney disease.[47,238,282,317] A trial that was reported in 2000 confirmed that even nonmicroalbuminuric type 2 diabetic patients should be managed with ACE inhibitors or ARBs to prevent cardiovascular events.[157] In addition to lowering systemic blood pressure, such patients also have lowered glomerular capillary blood pressure and protein filtration.[158,349,468] ACE inhibitors and ARBs also reduce AII-mediated effects on glomerular permeability and cell proliferation and fibrosis[255,291] and should be incorporated into the treatment schedules of all patients with type 2 diabetes and those with type 1 diabetes and microalbuminuria. ACE inhibitors may exacerbate hyperkalemia in patients with advanced CKD and/or hyporeninemic hypoaldosteronism. In older patients with renal artery stenosis, they may cause a rapid decline in kidney function. Pooled data from large clinical trials indicated above show that only 1.5% of patients treated with ACE inhibitors or ARBs were withdrawn from trials because of hyperkalemia, and no deaths were reported as a consequence of hyperkalemia.[47,238]

To achieve the target blood pressure values, there is often a need for four to five antihypertensive agents, including ACE inhibitors and ARBs, diuretics, beta-blockers, and calcium channel blockers. There may be additional benefits from combination therapy with ACE inhibitors and ARBs.[282] Although the renal risk in diabetic nephropathy can be reduced by 20% to 40%, the fact that 70% progress suggests that novel approaches are required. Experimental strategies identified in animal models could hold the key. However, if current recommendations for management are uniformly adhered to, along with statin treatment to reduce overall cardiovascular risk, then the goal of HP 2010 Objective 4.3 may be achieved.

Hypertensive Nephropathy

Hypertension is second only to diabetes as a primary diagnosis of ESRD for incident patients commencing dialysis in the United States.[427] From 1990 to 2000, there was a 32% increase in hypertension as the primary cause of ESRD. The incidence is higher in older people and especially among the black population in the United States. Hypertension often develops as a consequence of CKD because of alterations in salt and water metabolism and activation of the sympathetic nervous and renin-angiotensin systems.[116,241] Hypertension can act as an accelerating force in the development of ESRD. As described earlier, treatment of hypertension to predefined target blood pressure values is critical to preventing the progression to ESRD.[217,326,392]

Hypertension is grouped with large vessel *renovascular disease* in the USRDS Annual Data Report database. Primary diseases of the renal arteries usually involve the origin of the renal arteries at the aorta (ostial lesions). Secondary diseases with hypertension and CKD with small-vessel and intrarenal disease are referred to as "ischemic nephropathy." There is a complex interplay between renal artery stenosis and ischemic nephropathy. Atherosclerosis accounts for greater than 90% of renal artery stenosis. The disease is progressive and may cause renal artery occlusion.[57] The prevalence increases with age and is associated with refractory hypertension, low body mass index, smoking, diabetes, and established vascular disease elsewhere. In general, as a marker of established cardiovascular disease, atheromatous renal artery stenosis is associated with a poor prognosis.[260] Diagnosis requires a high index of suspicion and is guided by radiological examination of the renal arterial anatomy. Patients who receive ACE inhibitors and ARBs may develop ARF in the setting of severe bilateral renovascular disease or severe disease to a single functioning kidney. Kidney function should be carefully monitored following the introduction of these drugs. Deterioration in kidney function following introduction of these agents should also raise the suspicion of renovascular disease. The diagnosis is important to make since radiological displacement of intraluminal stents[32] is possible and surgical repair can be performed to prolong vessel patency.[149] Patients are at risk, however, of atheroembolism following intervention.[380]

Glomerular Diseases

In many patients, significant primary glomerular disease may be recognized by the presence of distinctive clinical syndromes that result from glomerular injury. Among the more important are rapidly progressive glomerulonephritis (RPGN), the nephrotic syndrome, acute nephritis, and chronic glomerulopathies. Systemic diseases that affect glomerular structure and function include for example systemic lupus erythematosus (SLE); microscopic polyangiitis; cryoglobulinemia; bacterial endocarditis; viral infections such as those associated with hepatitis B, C, and HIV; and malignancy. Diabetes and immunoglobulin light chain mediated kidney disease are discussed separately. A discus-

sion of all these syndromes is beyond the scope of this book. Examples serve to illustrate the use of the laboratory in their evaluation.

Primary glomerular disease presents clinically with (1) abnormalities of the urine, including proteinuria and hematuria, (2) hypertension, (3) edema, and often (4) reduced renal excretory function. Urinalysis should be ordered for patients presenting with hypertension or renal impairment or suspected of having kidney disease. Urinary casts are identified by microscopy, and red cell casts are indicative of glomerular bleeding and glomerular pathology. Specialist nephrology input is often required since histological examination of a kidney biopsy specimen, including immune reactants and electron microscopy, is usually performed to confirm the diagnosis.

Laboratory investigations performed to investigate glomerular disease and systemic disorders include (1) urinary protein excretion, (2) plasma creatinine concentration, (3) urea concentration, (4) liver function tests, (5) glucose concentration and, if myeloma is suspected, (6) serum protein electrophoresis, and (7) urinary examination for Bence Jones protein. Serological testing for the presence of autoantibodies to (1) antinuclear antigens (ANA), (2) double-stranded DNA (ds-DNA), (3) extractable nuclear antigens (ENAs), and (4) antineutrophil cytoplasmic antibody (ANCA) is performed if either SLE or systemic vasculitis is suspected. Antiglomerular basement membrane antibodies (anti-GBM) may be detected in rare cases of renal-limited anti-GBM disease (Goodpasture's disease) and pulmonary-renal syndromes (Goodpasture's syndrome). Components of the complement system can be affected (e.g., reduced levels of C3 and C4) in several conditions including SLE, infection, cryoglobulinemia, and mesangiocapillary (also referred to as membranoproliferative) glomerulonephritis. Blood cultures are taken for bacteriological examination in suspected infection.

The glomerular capillaries appear to be particularly vulnerable to immune-mediated injury, probably as a consequence of their unique function and structure. Continuous production of a protein-free filtrate across a complex capillary wall and a specialized mechanism for clearing trapped molecules through the mesangium increase the susceptibility by trapping circulating macromolecules. Deposition or generation of immune complexes can cause complement fixation and activation of lymphocytes and macrophages, all of which can mediate damage.[62] Resolution of inflammation may lead to normal tissue or kidney scarring. In some syndromes, well-characterized antigens are involved, such as the α-3 chain of type IV collagen in Goodpasture's syndrome, but in others their involvement is less clear.[219] There is evidence that environmental toxins and in particular organic solvents can increase the incidence of glomerulonephritis in Goodpasture's syndrome.[35] This might be from damage to the basement membrane lining the lung, which has some antigenic epitopes similar to those of the glomerular basement membrane. The environment plays a critical role in determining whether anti-GBM antibodies cause lung injury, since pulmonary hemorrhage only occurs in current cigarette smokers.[94]

The primary glomerulonephritides are classified morphologically according to histological analysis into subtypes with particular patterns of glomerular injury. There may be associated immune complex deposition (e.g., diffuse, focal/segmental, mesangiocapillary, and crescentic). Representative drawings from biopsy specimens from some of these conditions are shown in Figure 45-14 to show how

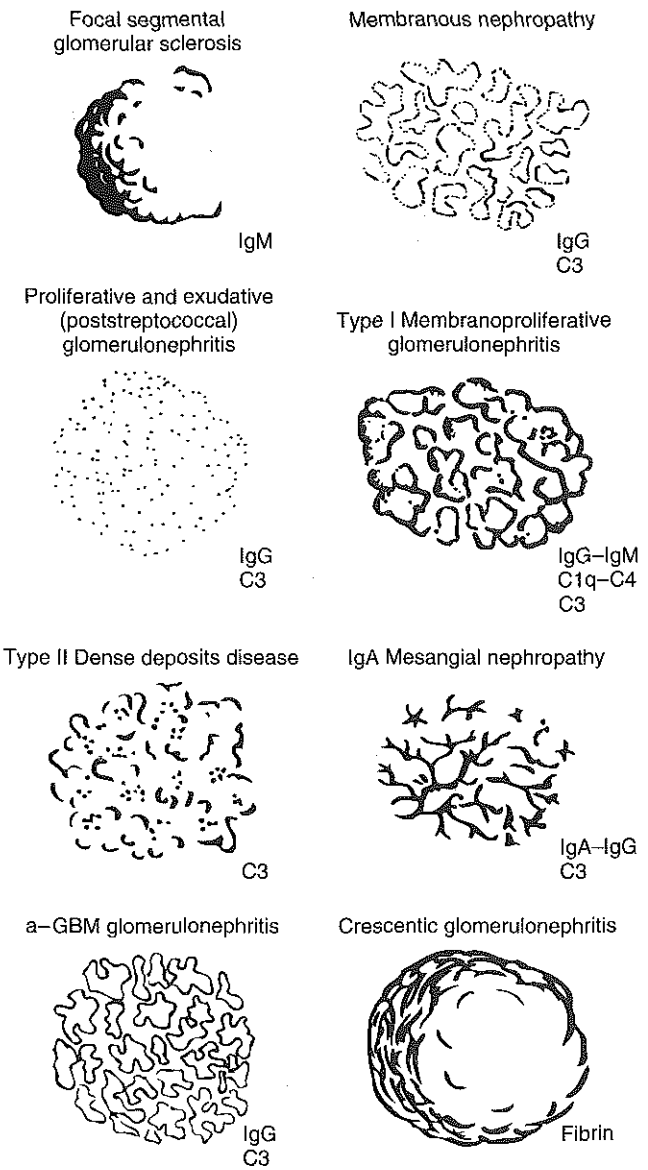

Figure 45-14 Glomerular pathology in glomerular nephritis, showing immunohistological patterns of the different types of primary glomerulonephritis. *(From Ponticelli C, Mihatsch MJ, Imbasciati E. Renal biopsy: performance and interpretation. In: Cameron JS, Davison AM, Grunfeld J-P, Kerr D, Ritz E, eds. Oxford textbook of clinical nephrology (vol. 1). 1st ed. Oxford: Oxford University Press, 1992:Chapter 1.7.2. Reproduced by permission of Oxford University Press.)*

clearly biopsy findings can distinguish different pathological conditions. However, there may be overlap in presentation, treatment, and outcome.

Glomerular diseases that are not amenable or that do not respond to treatment are chronic and often progressive. Glomerular disease eventually affects the blood supply of tubules and results in the loss of complete nephrons to produce advanced CKD and the uremic syndrome. In the United Kingdom, glomerulonephritis accounts for 13.6% of new patients to RRT in patients aged less than 65 years and 6.1% in older patients.[425] General measures to limit progression of CKD have been identified earlier and include tight blood pressure control and use of ACE inhibitors and ARBs.

IgA Nephropathy

IgA nephropathy is the most common type of glomerulonephritis worldwide. The disease tends to be slowly progressive and in 20 years 30% to 40% of patients will develop ESRD depending, as with most kidney diseases, on the degree of proteinuria and GFR at time of diagnosis and degree of interstitial fibrosis on biopsy. Biopsy findings are pathognomonic with deposition of polymeric immunoglobulin A (IgA). Up to 50% of patients exhibit elevated concentrations of plasma IgA, although diagnosis depends on kidney biopsy findings. Current treatment strategies are unsatisfactory, but involve general measures to reduce proteinuria, and prednisolone in selected cases.[335,404] Cytotoxic therapy can be considered for rapidly progressing or vasculitic IgA.[14]

Rapidly Progressive Glomerulonephritis

RPGN is a heterogeneous group of disorders characterized by a fulminant clinical course that leads to kidney failure in only weeks or a few months. These syndromes are often characterized by focal necrotizing glomerulonephritis and extracapillary crescent formation within the parietal layer of Bowman's capsules. Proliferating epithelial cells and macrophages eventually compress the glomeruli and obstruct the proximal convoluted tubules, thus severely compromising nephron function. The proliferation of epithelial cells and macrophages is in response to fibrinogen and fibrin polymers present in Bowman's space. This is a nonspecific reaction to severe glomerular injury attended by leakage of fibrinogen, activated enzymes, and macrophages out of the capillaries into Bowman's space. Crescents and deterioration in kidney function may develop rapidly.

RPGN may be classified either as idiopathic kidney disease or as a disease secondary to other conditions, such as infectious diseases, multisystem diseases, and occasionally an adverse reaction to medication. Anti-GBM antibodies may be present along the glomerular basement membrane in anti-GBM disease. Most commonly, however, there is no immunoglobulin deposition within the glomerulus (pauci-immune). Approximately 80% of patients with active pauci-immune necrotizing and crescentic glomerulonephritis have been shown to possess antineutrophil cytoplasmic antibodies (ANCA), irrespective of the presence or absence of a concomitant systemic vasculitis. This strong association has allowed serological discrimination of this type of glomerulonephritis from other types of RPGN. Wegener's granulomatosis, microscopic polyangiitis, and Churg-Strauss syndrome are small vessel vasculitides characterized by an association with ANCA.

ANCA were first reported in 1982 in patients with pauci-immune serological glomerulonephritis.[83] Three years later ANCA were detected by indirect immunofluorescence on normal human neutrophils in patients with active Wegener's granulomatosis.[429] Since 1989, two subtypes of ANCA have been described: cytoplasmic (C-ANCA) and perinuclear (P-ANCA), reflecting the patterns observed by indirect immunofluorescence microscopy using alcohol-fixed neutrophils as a substrate.[450] C-ANCA are directed toward a plasma proteinase (PR3) in neutrophil primary granules and are associated with Wegener's granulomatosis, whereas the P-ANCA target antigen is usually myeloperoxidase (MPO) and is associated with microscopic polyangiitis.[102,301] Enzyme-linked immunosorbent assays (ELISA) have been used to measure the anti-PR3 and anti-MPO antibody titers. Vasculitis or angiitis is an inflammatory reaction in the wall of any blood vessel and can have diverse clinical presentations. The exact sequence of events that triggers perivascular inflammation leading to injury is unclear, but ANCA have been identified that have at least diagnostic and prognostic usefulness. ANCA appear in the plasma of almost all patients with active and generalized disease. If unrecognized, these diseases can progress very rapidly to ESRD. However, effective treatments are available including high dose steroids, cytotoxic therapy, and plasma exchange.[205] This form of kidney disease accounts for 15% of patients presenting to specialist nephrology units for RRT and is therefore an important disease category to be aware of since, if treatment is initiated early, independent kidney function can be restored, particularly if active lesions are seen on biopsy.[154] In addition to the measurement of ANCA, C-reactive protein (CRP) may be used to monitor the acute phase reaction in active disease processes, together with tests for the general assessment of progressive kidney disease, including proteinuria.[370]

Nephrotic Syndrome

Gross changes in glomerular permeability characterize the nephrotic syndrome. The diagnostic criteria for establishing nephrotic syndrome are the presence of proteinuria (total protein >3 g/day or albumin >1.5 g/day), hypoalbuminemia, hypercholesterolemia, and finally edema. The edema was classically thought to be a consequence of the decreased intravascular oncotic pressure because of the loss of protein. However, expansion of the interstitial compartment is secondary to an accumulation of sodium in the extracellular compartment with reduced urinary sodium output, along with alterations of fluid transfer across capillary walls.[86] As shown in Figure 45-15, the proteinuria is a consequence of a reduction in the charge-selective properties of the filtration barrier, particularly the basement membrane and alter-

ations in the slit diaphragms of interdigitating foot processes of adjacent podocytes (epithelial cells).[96,348] Nephrotic syndrome can result from a variety of causes, including minimal change nephropathy (most common in children); focal segmental glomerulosclerosis (FSGS), membranous nephropathy, which may be idiopathic or associated with carcinoma, drugs, or infection; SLE; and diabetic nephropathy. Nephrotic syndrome in children characteristically responds to steroids if associated with highly selective proteinuria (predominantly albuminuria). Following histological confirmation of the underlying cause of the nephrotic syndrome therapy is targeted to reduce proteinuria and prevent predictable complications, such as hypercholesterolemia and venous thrombosis. High dose steroids and second line therapy with cyclophosphamide and cyclosporine may be initiated for refractory disease. Repeated treatment courses are necessary in relapsing disease.

Acute Nephritic Syndrome

This disorder is characterized by the rapid onset of hematuria, proteinuria, reduced GFR, and sodium and water retention, with resulting hypertension and localized peripheral edema. Congestive heart failure and oliguria may also develop. Renal biopsy shows enlarged, inflamed glomeruli with narrowed capillary lumina.

In a number of patients with the acute nephritic syndrome, the pathological process is related to recent group A β-hemolytic streptococcal infection of the pharynx or, less commonly, the skin. Only certain strains of streptococci are capable of inducing acute nephritis. A latent period averaging about 2 weeks exists between the streptococcal infection and clinical evidence of nephritis; it is slightly longer for cutaneous than for pharyngeal-associated disease. Typical poststreptococcal glomerulonephritis is now rare in developed countries. The initial presentation usually consists of oliguria, hematuria, hypertension, and facial and hand edema, with some evidence of vascular congestion. The presentation may vary considerably from patient to patient. Percutaneous renal biopsy of patients with poststreptococcal glomerulonephritis reveals enlarged hypercellular glomeruli infiltrated by polymorphonuclear leukocytes and monocytes, usually within the mesangium or capillary lumina. Proliferation of mesangial and endothelial cells is also observed. Involvement of the kidneys is diffuse. Electron

microscopy reveals deposits, presumably immune complexes, on the epithelial side of the basement membrane. Glomerular injury with damage to the glomerular basement membrane leading to a reduction in GFR is thought to be caused by activation of the inflammatory response by immune complexes.[453] Abnormal laboratory results are usually present early in the course of acute nephritis. Hematuria, gross or microscopic, and proteinuria, usually less than 3 g/day, are almost always present. Red blood cell casts are highly suggestive of glomerulonephritis. These casts are commonly present in urine but are observed only if the specimen is fresh and acidic, centrifugation is light, and sediment (after decantation) is resuspended gently. Large numbers of hyaline and granular casts are also common; waxy casts suggest a chronic process and should raise the possibility of acute exacerbation of a preexisting disease.

In patients suspected of having acute poststreptococcal glomerulonephritis, evidence of recent infection may be found in increased titers of antibodies to streptococcal extracellular products-antistreptolysin O (ASO), antihyaluronidase (AHase), and antideoxyribonuclease-B (ADNase-B). Serial measurements that document rising antibody titers against streptococcal antigens are stronger evidence of recent infection than a single determination. Most patients have moderate reductions in total hemolytic complement activity (CH_{50}) and in the C3 component of the complement cascade. Persistent and severe depression of C3 levels should suggest membranoproliferative glomerulonephritis, SLE, endocarditis, or other forms of sepsis. Although depressed levels of complement imply disease activity, they are not useful for grading the severity or determining the prognosis of the illness.

Other causes of acute nephritis are reactions to drugs, acute infection of the kidneys, systemic diseases with immune complexes such as SLE, bacterial endocarditis, and finally disease in which the antigen is unknown but possibly related to antecedent viral infections.

Primary glomerular diseases may recur following kidney transplantation and result in loss of the graft. An Australian study has confirmed a 10-year incidence of graft loss caused by recurrent glomerulonephritis as 8.4%.[48] Recurrence was the third most frequent cause of graft loss (chronic allograft nephropathy and death with a functioning graft were the most common). As compared with the average for all recipients with a primary diagnosis of glomerulonephritis, FSGS (11.8%) and mesangiocapillary glomerulonephritis type 1 (10.2%) were most likely to recur and cause graft loss. In contrast, graft loss because of recurrent IgA and pauci-immune crescentic glomerulonephritis occurred in only 2% of patients at 10 years follow-up.

Interstitial Nephritis

A variety of chemical, bacterial, and immunological injuries to the kidney cause either generalized or localized changes that primarily affect the tubulointerstitium rather than the glomerulus. This group of disorders is characterized by alterations in tubular function that, in advanced cases, may cause secondary vascular and glomerular damage. Interstitial nephritis, including chronic pyelonephritis, is the primary diagnosis, accounting for 3.8% of patients admitted onto dialysis programs in the United States.[427] In the United Kingdom the number is nearer 10%.[425] Pyelonephritis is the term associated with a bacterial infection that causes this kind of damage and is the most common of the interstitial nephritides.[411] There are both acute and chronic types of pyelonephritis, with the acute type most commonly associated with urinary tract infection. This can then develop into chronic pyelonephritis, usually as a result of a renal tract abnormality, such as abnormal urethral valves. Interstitial nephritis is also associated with proteinuria that is less severe than in glomerular disease. In addition to conventional pyelonephritis, interstitial nephritis may present in acute and chronic forms and has many causes. Acute interstitial nephritis presents with ARF and marked inflammation of the interstitium. Lymphocytes, polymorphonuclear cells, and eosinophils are prominent. The incidence is variable and depends on kidney biopsy practice. It may account for up to 7% of cases of ARF when an intrinsic kidney disease is diagnosed as opposed to purely toxic and/or ischemic acute tubular damage.[337] Higher values are likely in older people because of the increased incidence of drug reactions. A drug hypersensitivity reaction is the most common form of acute interstitial nephritis. Urinary findings may be normal or there may be low-level proteinuria and eosinophils can be seen on light microscopy. More than 100 different drugs have been implicated but NSAIDs and β-lactam antibiotics are the drugs most commonly identified.[121] Nephrotic syndrome may accompany an acute interstitial nephritis associated with NSAIDs. Treatment is directed at removing any causative agent. Steroids are used to promote early resolution of clinical course although patients can develop chronic interstitial fibrosis.[379]

Sarcoidosis is a multisystem disorder associated with chronic granulomatous interstitial nephritis. Biochemical abnormalities include hypercalcemia, hypercalciuria, and elevated serum ACE activity.[357] The condition may be effectively treated with steroids.

Polycystic Kidney Disease

Autosomal dominant polycystic kidney disease (ADPKD) is the second most common inherited monogenic disease (after familial hypercholesterolemia), with an estimated incidence of 1:1000. It is by far the most common inherited kidney disease.[118] According to data from the United Kingdom Renal Registry Report (2002), ADPKD is responsible for almost 9% of new ESRD in patients aged less than 65 years and 3.3% of incident patients over age 65.[425] The prevalence of the disease ranges from 1 in 200 to 1 in 1000 of the population, but many cases, possibly up to 50%, remain clinically undiagnosed during life. The disease causes the development of multiple kidney cysts and extrarenal cysts occurring in the liver and pancreas. About 10% of

ADPKD families have a strong family history of intracranial artery aneurysm rupture. Hypertension is an early and frequent manifestation, and gross hematuria is a common presenting symptom.

Approximately 50% of ADPKD patients develop ESRD by age 55.[118] An important clinical observation is the highly variable phenotype within families. The two major genes mutated in ADPKD, *PKD1* and *PDK2*, have been identified.[179,214,346] The most common mutation (found in 86% of cases) is the *PKD1* mutation on chromosome 16, which codes for an abnormal form of the protein polycystin (460 kDa), which has been shown to have a role in epithelial cell differentiation, regulation of cell adhesion, and apoptosis. Other mutations include the *PDK2* mutation on chromosome 4 (110 kDa) and APKD3, for which the gene product and chromosomal location remain as yet unknown.[319] *PKD2* appears to be a more slowly progressing form of the disease.[153] The median age of onset of ESRD with *PKD2* is 15 years later than *PKD1*. There is also a rare (incidence 1/20,000) autosomal recessive form of the disease that presents in childhood.

Toxic Nephropathy

A wide variety of nephrotoxins exist in the environment, many of which are associated with particular occupations. A variety of heavy metals, such as cadmium and lead, have long been known to be associated with kidney disease, often causing proximal tubular dysfunction and glomerular damage (see Chapter 35).[466] A summary of the drugs and environmental toxins known to cause kidney damage is given in Table 45-11. Both glomerular and tubulointerstitial damage result from exposure to these toxins; detection of both requires biochemical monitoring of GFR and tubular and glomerular proteinuria.

Obstructive Uropathy

Benign prostatic hypertrophy (BPH) is one of the most common types of obstructive uropathy and an almost universal finding in aging men.[276] For example, for men over 50 years, the reported prevalence of BPH varies between 50% and 75%, but there is no close relationship between the degree of enlargement and the symptoms experienced.[67] Among the most common symptoms are disorders of micturition, in particular increased frequency, and in many cases this can progress to bladder outflow obstruction. Between 10% and 40% of men with bladder outflow obstruction caused by BPH present in acute retention.[276] Approximately 5% of this group have high-pressure chronic retention of urine, which can result in upper urinary tract obstruction and consequently CKD as a result of glomerular and tubular damage. Although medical treatments are available to decrease the rate of enlargement of the prostate, resection of the enlarged gland remains the most common surgical procedure performed on men. Urinary retention can be a chronic disorder with acute exacerbations requiring bladder decompression by catheterization. If the obstruction is not removed by operation, progressive kidney injury can occur as a result of backpressure along the urinary tract. It is important to identify those patients at risk of developing CKD, because failure to remove their enlarged gland can cause ESRD. Obstruction can also occur because of kidney stones, which can cause bilateral or unilateral damage. In children severe kidney damage can be caused by vesicoureteric reflux. One of the main complications of reflux, whether caused by obstruction or by an inherited defect, is the increased incidence of urinary tract infection. When the obstruction is relieved the kidney often regains some independent function. There is a tendency to slower progression to ESRD in obstructive uropathy compared with other kidney diseases.

Tubular Diseases

Types of tubular disease discussed in this section include renal tubular acidoses and inherited tubulopathies.

Renal Tubular Acidoses

The renal tubular acidoses (RTAs) comprise a diverse group of both inherited and acquired disorders affecting either the proximal or distal tubule. They are characterized by a hyperchloremic, normal anion gap; metabolic acidosis; and urinary bicarbonate or hydrogen ion excretion inappropriate for the plasma pH. They are the result of either failure to retain bicarbonate or inability of the renal tubules to secrete hydrogen ion. Typically the GFRs in RTAs are normal, or slightly reduced, and there is no retention of anions, such as phosphate and sulfate (as opposed to the acidosis of renal failure). Before attempting to understand the pathology of these conditions, the reader should ensure a good comprehension of normal renal acid-base (and ammonia) regulation (see Chapter 46).

Classification

The classification of the RTAs is based upon the biochemical expression and region of defect rather than an understanding of the exact molecular defect. The three categories of RTA are distal (dRTA, type I); proximal (pRTA, type II); and type IV, which is secondary to aldosterone deficiency or resistance. The term "type III RTA" (mixed proximal/distal defect) has been abandoned as it is no longer considered a separate entity.[123,324]

Distal RTA (Type I). Type I dRTA occurs most often in infants (sometimes transiently) or young children, but it may also be encountered in adults, where it is more common than pRTA. Clinical features generally include a metabolic acidosis, muscle weakness, nephrocalcinosis, and urolithiasis. The defect is an inability to secrete hydrogen ions in the distal tubule in the presence of a systemic acidosis. Several subtypes may be seen: urinary pH >5.5 is a common feature.[324]

Classic (Hypokalemic, Secretory) dRTA. The molecular basis is not known, but may include defects in the H^+-ATPase or H^+, K^+-ATPase transporters. dRTA may occur in association with a wide range of conditions, including (1) an

TABLE 45-11 Drugs and Environmental Toxins Associated With the Development of Nephropathy

Drug	Toxic Action
ACE inhibitors	Drastic drop in GFR in patients with bilateral renal artery stenosis High-dose captopril can cause proteinuria
NSAIDs/COX-2 inhibitors	Drastic drop in GFR in patients with circulatory insufficiency (e.g., cardiac failure) Hypovolemia; can also cause acute and chronic interstitial nephritis
Antirheumatoid drugs	
Calcineurin inhibitors (cyclosporine and tacrolimus)	Vasoconstriction, glomerular vasculopathy, and interstitial fibrosis
Gold salts	Membranous-type picture with nephrotic syndrome (mechanism unknown)
Mercury compounds	Membranous-type picture with nephrotic syndrome (mechanism unknown)
D-penicillamine	Membranous-type picture with nephrotic syndrome (mechanism unknown)
Antitumor drugs	
Mitomycin	Hemolytic-uremic syndrome
Cisplatin	Acute tubular necrosis
Methotrexate	Intraluminal precipitation and acute tubular necrosis
Antibiotics/antifungals	
Aminoglycosides	Acute tubular necrosis and interstitial nephritis[240]
Cephalosporins	Interstitial nephritis
Penicillin G	Interstitial nephritis
Ampicillin	Interstitial nephritis
Amoxicillin	Interstitial nephritis
Amphotericin	
Lithium	Distal tubular damage with nephrogenic diabetes insipidus
Allopurinol	Interstitial nephritis
Environmental toxins	
Mercury	Glomerulonephritis
Cadmium	Chronic interstitial nephritis
Lead	Hypertension and tubulointerstitial nephritis
Chromium	Increased tubular proteins and enzymuria
Vanadium	Increased tubular proteins and enzymuria
Nickel	Increased tubular proteins and enzymuria

ACE, Angiotensin converting enzyme; *NSAIDs*, nonsteroidal antiinflammatory drugs.

autosomal dominant condition (more common in females); (2) a sporadic, nonfamilial disease; (3) other genetic disorders (e.g., Wilson's disease); (4) dysproteinemias (e.g., hypergammaglobulinemia, cryoglobulinemia, amyloidosis); (5) disorders of calcium metabolism (e.g., primary hyperparathyroidism); and (6) a range of autoimmune disorders (e.g., SLE, Sjögren's syndrome, primary biliary cirrhosis, thyroiditis). The pathogenesis of nephrocalcinosis and urolithiasis may be the result of decreased urinary citrate excretion secondary to cellular acidosis.

Back-Leak dRTA. Although the kidney tubule retains the ability to secrete hydrogen ions, the gradient is not maintained because of back diffusion. Typically, this occurs in association with specific drug treatments (e.g., amphotericin B).

Voltage-Dependent (Hyperkalemic) dRTA. This is due to failure to maintain an intraluminal negative potential and thus promote hydrogen (and potassium) ion secretion. This may be seen with urinary tract obstruction, sickle cell disease, and treatment with amiloride or triamterene. This condition has many features in common with type IV RTA (see discussion later in this chapter). It is frequently associated with mild to moderate CKD, and hyperkalemia is caused in part by the decreased GFR in addition to decreased potassium excretion relative to the filtered load. In contrast to classic dRTA, potassium excretion cannot be increased in response to sodium sulfate (Na_2SO_4) administration, suggesting an isolated defect in hydrogen ion secretion. However, because hydrogen ion secretion is dependent on sodium reabsorption in the distal tubules, the primary defect could also be an impairment of distal tubular sodium reabsorption.

Incomplete dRTA. This is a less severe, normokalemic form, which may represent an early stage of overt dRTA.

Some patients acidify urine at a submaximal rate, but at a rate that is generally sufficient to maintain acid-base balance. Potassium wasting, hypokalemia, and hyperchloremia are generally not present. However, when patients are stressed or are given an acid load, their ability to excrete acid and to lower urine pH is suboptimal and urinary pH may exceed 5.5.

Proximal RTA (Type II). In pRTA the primary defect is failure of proximal tubular bicarbonate reabsorption. This may occur as an isolated defect (primary or sporadic type II pRTA) that occurs chiefly in infant males and is commonly associated with growth retardation, or that produces a general Fanconi syndrome. Acquired diseases that may also produce a Fanconi syndrome and pRTA include multiple myeloma, Sjögren's syndrome, amyloidosis, heavy metal poisoning, and renal transplant rejection. Drugs that act as carbonic anhydrase inhibitors (e.g., acetazolamide and topiramate) have also produced a pRTA condition. (Note that several of these disorders and agents also cause dRTA.) In pRTA the threshold for bicarbonate reclamation is lowered (from a plasma concentration of 22 mmol/L to 15 mmol/L).[324] Once plasma bicarbonate falls below this threshold, filtered bicarbonate is reclaimed, and urinary pH will generally be <5.5. In pRTA, contrary to dRTA, nephrocalcinosis and nephrolithiasis are rarely observed but metabolic bone disease is common. Other features of the Fanconi syndrome (e.g., glycosuria, aminoaciduria, hypophosphatemia, and hypouricemia) are commonly present.

Selective Aldosterone Deficiency (Type IV RTA). In type IV RTA, there is failure of distal potassium and hydrogen ion secretion because of aldosterone deficiency or resistance. This may occur because of a range of steroid or steroid receptor synthetic defects or because of hyporeninemic hypoaldosteronism (e.g., due to diabetic nephropathy, tubulointerstitial disease, urinary obstruction, renal transplantation, or SLE). Hyperkalemia, although mild, is a usual manifestation.

Diagnosis of RTA

The finding of a hyperchloremic metabolic acidosis in a patient without evidence of gastrointestinal bicarbonate losses and with no obvious pharmacological cause should prompt suspicion of an RTA. The presence of suggestive clinical (e.g., nephrocalcinosis in dRTA) or biochemical (e.g., hypophosphatemia and hypouricemia as a result of proximal tubular wasting in pRTA) features should also be considered.

In addition to plasma electrolyte (including potassium) measurement, preliminary investigation should include measurement of urinary pH in a fresh, early morning urine sample. The finding of a urine pH > 5.5 in the presence of a systemic acidosis supports the diagnosis of dRTA, although it is not specific and will also be seen in types II and IV RTAs. If appropriate urinary acidification cannot be demonstrated, further investigation may involve assessing the kidneys' ability to excrete an acid load (ammonium chloride load test) and reabsorb filtered bicarbonate (fractional bicarbonate excretion). Further details of the conduct and interpretation of these tests may be found in the 1999 review by Penney and Oleesky.[324]

Treatment of RTA

Treatment of the RTAs is aimed at (1) correcting the biochemical disturbance and, where possible, underlying disorder, (2) improving growth in children, and (3) avoiding the development and progression of CKD. In both type I and II RTAs, bicarbonate is administered to correct the metabolic acidosis. Fludrocortisone and loop diuretics may be used to treat type IV RTA.

Inherited Tubulopathies

The inherited tubulopathies comprise a heterogeneous set of disorders often characterized by electrolyte disturbances. Most are eponymous and have been described clinically for many years. However, increased understanding of the molecular biology of tubular ion channel and transport pumps has now delineated the mechanism of disease in many of these disorders. In addition to electrolyte disturbances (particularly of potassium), general reasons to suspect a tubulopathy include a familial disease pattern, renal impairment, nephrocalcinosis, and stone formation, especially if these should present at an early age. In cases in which a diuretic-sensitive channel is affected, these disorders will clearly mimic the effects of diuretic use (see discussion later in this chapter) and exclusion of covert use of diuretics is important. Although individually uncommon or rare, an awareness of these disorders is critical for the clinical biochemist when considering the potential differential diagnoses in patients presenting with electrolyte imbalances. A brief description of these disorders follows; for more detailed information the reader is referred to the citation list, including several reviews of this subject.[321,371,374] This section should be considered in conjunction with the aforegoing description of tubular electrolyte handling (see "Electrolyte Homeostasis").

Bartter's Syndrome

This is a group of autosomal recessive disorders characterized by (1) renal salt wasting, (2) polyuria, (3) polydipsia, (4) impaired urinary concentrating ability, (5) a hyperreninemic, hypokalemic metabolic alkalosis, and (6) a mild hypomagnesemia in some patients. Biochemically the effects resemble those of loop diuretic use, but clinically the phenotype is highly variable. This arises because of the fact that the syndrome encompasses defects of three different transporters/channels in the loop of Henle. The biochemical effects are predictable from knowledge of the function of these transporters and channels (see Figure 45-7).

Mutations in the genes encoding for NKCC2 (type I) or ROMK1 (type II) are associated with the more severe phenotype, including polyhydramnios, premature birth, life-threatening salt wasting in the perinatal period, and

hypercalciuria. Patients with ROMK1 defects tend to have less severe hypokalemia.

The milder ("classic," type III) Bartter's syndrome is due to defects in the basolateral pump CLC-Kb. Although the phenotype is extremely variable (neonatal, life-threatening presentations do occur), these patients typically present in the first year of life with weakness and hypovolemia and normal urinary calcium excretion. Nephrocalcinosis and kidney stone formation are not normally features.

Gitelman's Syndrome

This autosomal recessive disorder is also characterized by a hypokalemic, hyperreninemic, hypomagnesemic, metabolic alkalosis but presentation is generally much later in life than in Bartter's syndrome and hypocalciuria is typical. Clinical features include reduced blood pressure, weakness, paresthesia, tetany, fatigue, and salt craving.[16] The urinary calcium:creatinine excretion ratio can be useful in distinguishing between Gitelman's and Bartter's syndromes. The molecular defect is in the thiazide-sensitive NCCT transporter and the biochemistry can therefore mimic the effects of thiazide use (see Figure 45-7).

Liddle's Syndrome

This autosomal dominant disorder is also characterized by a hypokalemic, hypomagnesemic metabolic alkalosis but, in contrast to Bartter's and Gitelman's syndromes, there is hypertension and hyperreninism. The disease is due to activating mutations, which increase sodium transport through the ENaC channel with consequent enhanced kaliuresis (see Figure 45-8).

Pseudohypoaldosteronism Type I

This condition presents in infancy with salt wasting, hypotension, hyperkalemia, and significant hypereninism and aldosteronism. Two different molecular mechanisms are causative. Type Ia (autosomal recessive) is caused by inactivating mutations of the ENaC gene, while type Ib (autosomal dominant) is caused by mutations in the mineralocorticoid gene. In both cases, sodium loss in the collecting duct is increased with consequent retention of potassium.

Dent's Disease

Dent's disease is an X-linked condition characterized by hypercalciuria and kidney stone formation, low molecular weight proteinuria, aminoaciduria, hypophosphatemia, and rickets.[460] The disease arises from single-base change mutations, of which approximately 60 have been described, in the gene coding for the tubular chloride channel CLC-5. The exact relationship between the loss of function of this protein and the resulting Fanconi syndrome remains unclear.[410] Although X-linked, a mild form of the disease can be seen in females because of lyonization. The related syndromes (1) X-linked recessive nephrolithiasis, (2) X-linked recessive hypophosphatemic rickets, and (3) Japanese idiopathic low molecular weight proteinuria are also all related to defects in CLC-5.[410]

Phosphate Disorders

Several disorders of tubular phosphate handling have been described. The best known of these is X-linked dominant hypophosphatemic rickets (previously known as vitamin D–resistant rickets). This disorder arises because of a defect in the *PHEX* gene. A defect of the sodium-dependent/phosphate co-transporter has also been described, giving rise to autosomal recessive hereditary hypophosphatemic rickets with hypercalciuria. The molecular biology of these and other renal phosphate transport disorders has been reviewed.[408]

Other tubulopathies beyond the scope of this textbook include (1) hypomagnesemic hypercalciuric nephrocalcinosis ("congenital magnesium losing kidney"), (2) Gordon's syndrome (pseudohypoaldosteronism type II), (3) Lowe's syndrome (oculocerebral dystrophy), and (4) a series of disorders of the Ca-SR.[321,371,374]

Diuretics

Diuretics are among the most widely prescribed drugs. They are predominantly used to treat either hypertension and/or disorders associated with fluid overload. All diuretics act by interfering with tubular reabsorption of sodium and/or chloride and therefore have accompanying effects on water retention. Diuretics are taken up by tubular cells across the basolateral membrane by specific anion- (e.g., furosemide and thiazides) or cation- (e.g., amiloride and triamterene) exchangers and then secreted into the lumen by a process that has not been fully elucidated.[136] Different classes of diuretics act at different sites along the nephron. A basic understanding of these processes is helpful in understanding both the potency of different diuretic classes and their importance in the investigation of electrolyte disorders, in particular hypokalemia. Many diuretics will cause hypokalemia to some degree, depending on the potency, dose, duration of treatment, and the patient's underlying potassium balance.

Loop Diuretics

Loop diuretics act largely by blocking sodium and chloride reabsorption in the ascending limb of the loop of Henle. Since this is a site at which 30% of sodium reabsorption normally occurs, these are considered potent diuretics. Loop diuretics specifically inhibit NKCC2, and therefore also have an effect on potassium handling in the ascending limb. Consequent changes in transepithelial potential result in a direct kaliuretic effect in this region,[135] causing a hypercalciuria (see Figure 45-7). Loop diuretics also paralyze the macula densa segment, stimulating renin secretion and subsequent aldosterone release, further exacerbating the kaliuresis. Most significantly, blockage of loop sodium reabsorption results in enhanced delivery to the distal tubule, where sodium is reabsorbed in exchange for potassium secretion.[135] The affin-

ity of loop diuretics for NKCC2 is bumetanide = torasemide > piretanide > furosemide = azosemide.[136]

Thiazide Diuretics

The benzothiadiazine group of compounds inhibit NCCT in the distal tubule. Since only 5% to 10% of sodium reabsorption occurs at this site, they are less potent than the loop diuretics but hypokalemia is still common as a result of increased sodium delivery to the collecting duct. Thiazide diuretics also have secondary effects resulting in increased calcium reabsorption.[136]

"Potassium-Sparing" Diuretics

These diuretics act by reducing sodium reabsorption in the collecting duct, and hence increasing potassium retention. Spironolactone acts as a competitive antagonist of aldosterone, blocking its stimulatory effects on sodium reabsorption via the mineralocorticoid receptor. Amiloride and triamterene both inhibit ENaC. The danger of this group of diuretics is that they can induce hyperkalemia, which is particularly likely to occur in patients with kidney disease.

Diabetes Insipidus

Primary functions of the kidney include the conservation of water and production of a concentrated urine. A range of conditions are associated with disturbances of the renal concentrating mechanism, resulting in polyuria and an inability to produce hypertonic urine. General conditions giving rise to this picture include hypercalcemia, hypokalemia, and CKD. Specifically, diabetes insipidus (DI) is due to the absence of an ADH effect, either because of impaired or failed secretion (cranial or central DI) or lack of end-organ response to ADH (nephrogenic DI). A further disorder, psychogenic polydipsia or compulsive water drinking, can also present as diabetes insipidus. These individuals may fail to concentrate urine even in response to fluid restriction or synthetic ADH as a result of medullary "washout"; sustained fluid ingestion destroys the hyperosmolality of the medulla, which may take some time to recover. The differentiation and pathology of these three conditions are discussed in Chapter 50. It should be noted that a vast diuresis can also be induced by consuming excessive fluid volumes (e.g., heavy beer drinkers).

Congenital nephrogenic diabetes insipidus is associated with defects that have now been characterized at the molecular level.[27] Most (>90%) congenital nephrogenic DI patients have mutations in the *AVPR2* gene, which codes for the ADH V_2 receptor. This results in a rise to an X-linked form of DI, with an estimated prevalence of 4 per 1 million males.[27] In <10% of cases, there is an autosomal recessive inheritance pattern caused by mutations in the *AQP2* gene. It has been suggested that measurement of the urinary excretion of AQP may be useful diagnostically.[84,300] Acquired forms of DI are more common than congenital forms. Downregulation of AQP2 has been observed in a variety of acquired forms of DI, including lithium treatment, hypokalemia, hypercalcemia, ureteric obstruction, and in animal models, chronic kidney failure.[300]

Renal Calculi

Nephrolithiasis is the diseased condition associated with the presence of renal calculi. Renal calculi, commonly termed kidney stones, occur in the renal pelvis, the ureter, or the bladder. In developed countries, bladder stones are now uncommon, as the causative factors of malnutrition and infection have been eliminated.[365] Calcification can also occur scattered throughout the parenchyma (nephrocalcinosis). Kidney stone formation is often considered to be a nutritional or environmental disease, linked to affluence, but genetic or anatomical abnormalities are also significant. Approximately 5% to 10% of the population of the western world are thought to have formed at least one kidney stone by the age of 70 years[188,365] and the prevalence of kidney stones may be increasing.[400] In both males and females, the average age of first stone formation is decreasing (Robertson WG, personal communication). For most stone types, there is a male preponderance. The passage of a stone is associated with severe pain called renal colic, which may last for 15 minutes to several hours and is commonly associated with nausea and vomiting.[452] There is some evidence that stone formation contributes to the development of CKD.[122]

Background

Chemically, urine contains many mineral salts that are present in concentrations that approach their solubility products, and the solutions are metastable. Anyone who has seen a urine sample before and after refrigeration has witnessed the consequences of this in the massive crystal deposits that form on cooling. Crystals can form spontaneously if the salt concentrations are high enough, or alternatively, preformed nuclei can provoke their formation. Human urine contains a number of promoters of stone formation and a variety of inhibitors, the concentrations of which can be influenced by dietary and metabolic factors (Figure 45-16).

Initial diagnosis and investigation of stones require radiological investigations to explore the degree of intrarenal calcification and papillary damage. Plain x-rays are undertaken at initial presentation, although it should be noted that urate and other purine stones and some cystine stones are radiolucent. An intravenous urogram or spiral computed tomography scan may be performed to establish the presence and extent of urinary tract obstruction, intrarenal reflux, and ureteric dilation. Further investigation of the patient with kidney stones or suspected of being a stone former involves analysis of blood, urine, and the stone itself, should one be obtained.[73,163]

Small stones (<5 mm in diameter) pass spontaneously in the urine as "gravel."[452] Although surgical treatment to remove large staghorn calculi may still be necessary, the most common form of treatment is ultrasonic extracorporeal shock wave lithotripsy (ESWL),[338] which can be applied to

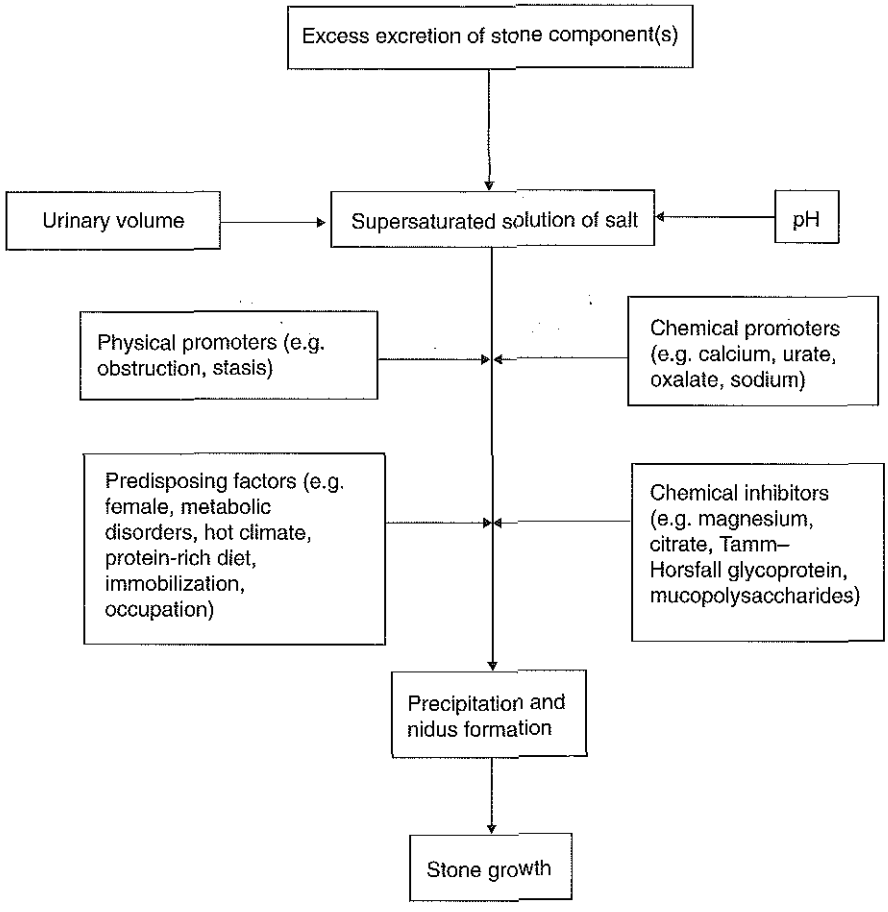

Figure 45-16 Diagrammatic representation of the interplay of factors involved in kidney stone formation. High or low pH may act as a promoter or inhibitor of stone formation depending on the stone type in question (e.g., calcium stone formation is favored by inadequate acidification while urate is less soluble in acidic urine). Controversy exists as to whether formed stones become trapped as they pass through the nephron ("free particle theory") or whether stone formation occurs at damaged sites on the tubule wall ("fixed particle theory").

stones between 5 mm and 2 cm in diameter. Although this allows noninvasive destruction of stones, the long-term sequelae of exposing the kidney to high-intensity sound waves have not been fully established.[122] Additionally, evidence is mounting that ESWL may be associated with higher recurrence rates than invasive treatment.[405] Percutaneous nephrolithotomy may be required if ESWL fails and also in the removal of cystine stones.

Following treatment and successful removal of a stone, follow-up monitoring is required, as many patients will have recurrent disease: in the absence of medical treatment the recurrence rate may be as high as 50% at 10 years.[247] The mechanisms responsible for the multiple recurrences of kidney stones in only certain individuals are not completely understood. Factors involved include (1) urine flow (fluid intake); (2) excretion of excess quantities of stone components; (3) the relative absence of a substance, or substances, in the urine that inhibit stone formation; and (4) urinary pH (see Figure 45-16). The predominant risk factor is poor hydration, a concentrated urine increasing the concentrations of the mineral salts further, predisposing to crystallization. This at least partially explains the increased incidence of kidney stone disease in hot climates, for example, in the Gulf states.

Kidney Stone Analysis

The majority of kidney stones found in the western world are composed of one or more of the following substances: (1) calcium oxalate with or without phosphate (frequency 67%), magnesium ammonium phosphate (12%); (2) calcium phosphate (8%); (3) urate (8%); (4) cystine (1% to 2%); and (5) complex mixtures of the above (2% to 3%).[365] These poorly soluble substances crystallize within an organic matrix, the nature of which is not well understood.

When available, analysis of the chemical constituents of stones may be useful in establishing the etiology and in planning rational therapy. It complements and guides metabolic investigation of the patients and may be particularly useful in identifying rare stone types (e.g., xanthine and dihydroxyadenine), artefacts (e.g., Munchausen syndrome), or drugs precipitating in the urinary tract, such as triamterene[398] and indinavir.[221] Conversely, it has been argued that stone analysis is not useful clinically,[162] since the stone material passed often does not represent the initial metabolic derangement. This is due to the phenomenon known as epitaxy, whereby nonspecific stone material, typically arising as a result of urinary tract infection (e.g., struvite), may accumulate on a preexisting "metabolic" nidus, the latter of which may not be detected during stone analysis. Clearly, for

stone analysis to be useful it must be accurate. A variety of techniques have been used over the years. Traditionally, stones were crushed, solubilized, and the resulting solution analyzed (at several dilutions when appropriate) using conventional qualitative or semiquantitative chemical methods. Such techniques require relatively large amounts of stone, may miss rare and artefactual material, and analytically often perform poorly.[365] More sophisticated approaches including thermogravimetric analysis,[359] x-ray diffraction crystallography, and particularly, infrared spectroscopy[23,166] are preferred.[206] A detailed description of the infrared method is beyond the scope of this chapter; the reader is referred to descriptions in the scientific literature.[23,166,206]

Metabolic Investigation of Kidney Stone Formers

Ensuring adequate fluid intake remains the cornerstone of management of stone disease. However, specific management of disease depending on the metabolic abnormality present is also important and a treatment rationale is emerging. There have been several misconceptions about the role of diet in stone formation and optimal treatment may, at first, appear counter-intuitive; some of these paradoxes are discussed below.

Further investigation of stone formers may be guided by knowledge of the type of stone formed. However, the increasing use of lithotripsy means that there is often no stone material available for analysis. Consequently a management strategy focusing on the cause of stone formation and based upon knowledge of blood and urinary composition is useful. Although historically, metabolic investigations have often been targeted at recurrent stone formers only,[73] the increasing availability of simple assays for chemical risk factors and the health-economic burden of renal colic suggest that they are likely to become more widespread.[162,339] However, in some instances, it is not possible to demonstrate a biochemical abnormality in stone-forming individuals beyond a persistently small urine volume.

A variety of metabolic screening strategies have been proposed in stone-forming patients.* The chosen strategy should balance convenience for the patient and the laboratory against ability to intervene therapeutically. For example, although Tamm-Horsfall glycoprotein is known to inhibit stone formation, in the absence of a specific treatment, there is little merit in quantitating it. A reasonable approach would probably include measurement of plasma sodium, potassium, chloride, bicarbonate, creatinine, calcium, phosphate, and urate together with 24-hour urinary volume, pH, calcium, magnesium, phosphate, oxalate, urate, creatinine, sodium, citrate, microbiology (to exclude infection), and cystine (screening test). Some investigators have proposed complex "supersaturation indices" that combine the information obtained from these studies in a numerical index.[316,355,412] Metabolic evaluation should be undertaken at least 6 weeks after the episode of renal colic and should ideally be done on several occasions.[165] It is most informative when undertaken on an outpatient basis with patients pursuing their normal diet and lifestyle. Urinary pH and cystine should be measured on a fresh, early morning urine sample. A brief description of the role and measurement of these risk factors is given below, focusing predominantly on the investigation of calcium stone formers.

Calcium

The majority of stones formed in the western world are composed of calcium, most commonly in association with oxalate although calcium phosphate and urate may also be present, either alone or in combination with calcium oxalate. As a consequence urinary calcium measurement has been the central investigation. However, the significant role of oxalate is increasingly appreciated and this has resulted in changes to the optimal management of hypercalciuria. As a rough guide, calcium oxalate stones tend to suggest hyperoxaluria as the main cause while calcium phosphate stones implicate hypercalciuria and/or failure to adequately acidify urine.[365] A strict definition of hypercalciuria is difficult as there is significant overlap between stone-forming and nonstone forming individuals but a cutoff of 0.1 mmol/kg body weight (4 mg/kg) is useful.[54] Excretion in excess of this is the most common metabolic abnormality seen in calcium stone formers, being observed in up to 50% of patients.

Traditionally, some investigation strategies focused on whether patients demonstrated hypercalciuria while fasting ("renal hypercalciuria") or in response to a calcium load ("absorptive hypercalciuria").[452] This classification was used as the basis of a treatment strategy in patients with absorptive hypercalciuria who have abnormally high intestinal calcium absorption compared with nonstone formers (possibly because of a relative increase in $1,25(OH)_2D_3$ concentrations and/or changes in intestinal vitamin D receptor activity). Treatment in these patients focused on dietary modification of calcium intake. Patients with renal hypercalciuria are now thought not to have a renal transport defect but to have increased turnover of skeletal calcium, although the management of such patients may involve pharmacological modification of renal calcium handling (e.g., thiazide diuretics).[452]

However, convincing evidence questions the usefulness of this classification and these therapeutic approaches. Dietary restriction of calcium is now generally regarded as ineffective, and actually counterproductive, as it results in an increase in intestinal oxalate absorption and increased risk of stone formation.[63,77] Further, patients with hypercalciuria are known to have reduced bone mineral density, and dietary calcium restriction may exacerbate a tendency to osteopenia and/or osteoporosis.[417,444]

A more useful approach is to classify hypercalciuric patients into either hypercalcemic or nonhypercalcemic causes. The former is most commonly due to primary hyper-

*References 73, 163, 165, 339, 365, 413.

parathyroidism, which is seen in approximately 5% of stone formers. Treatment involves neck exploration and removal of the adenoma, although the risk of a stone recurring remains high for several years after parathyroidectomy.[284] Nonhypercalcemic causes of hypercalciuria constitute the majority of patients and are generally classified as idiopathic (although causes such as RTA, high sodium intake, and prolonged immobilization should be excluded). In addition to increasing fluid consumption, idiopathic hypercalciuric patients appear to benefit from a diet that is low in animal protein and sodium.[41,354] Animal protein consumption increases the production of metabolic acids, increasing urinary calcium excretion and decreasing urinary citrate (see discussion later in this chapter).[54] It also increases uric acid excretion. High sodium excretion as a result of high consumption inhibits tubular reabsorption of calcium, with a consequent increase in risk of calcium stone formation. Sodium is easily and cheaply measured in urine and represents a modifiable risk factor. Other therapeutic maneuvers that may be useful include the use of thiazide diuretics or alkaline citrate, reducing oxalate, and increasing fiber intake.[413] Some of these factors are discussed in more detail below.

Magnesium

With calcium stone disease, magnesium is an inhibitor of stone growth. Magnesium forms complexes with oxalate that are more soluble than calcium oxalate. Increased urinary magnesium therefore inhibits stone formation.[146] Administration of magnesium has been shown to reduce enteral calcium absorption and has been proposed as a treatment for idiopathic hypercalciuric stone formers.[87] However, oral magnesium supplementation may have unpleasant side effects and a positive benefit in terms of reducing stone recurrence has not been demonstrated.[413]

Urate

Some investigators believe that urate may potentiate calcium stone formation, although this perception is not universally accepted.[365] However, hyperuricosuria is common in calcium stone–forming patients, and treatment with allopurinol, thereby decreasing urate synthesis, reduces the rate of stone recurrence. Allopurinol treatment is therefore recommended for hyperuricosuric patients with calcium stone disease.[413] The formation and management of pure urate stones are discussed in Chapter 24.

Oxalate

Oxalate is an end product of metabolism, predominantly derived from breakdown of glyoxylate and glycine. Plasma concentration of oxalate is 1.0 to 2.4 mg/L (11 to 27 μmol/L) and it is excreted in the urine at a rate of 17.5 to 35.1 mg/24 hours (200 to 400 μmol/24 hours).[457] Only 10% to 15% of urinary oxalate is derived directly from dietary sources.[413] Intestinal oxalate absorption is increased when the availability of calcium in the intestine is reduced. Hyperoxaluria is a powerful promoter of calcium oxalate stone formation; indeed, it is more significant in this respect than calcium itself.[365] Hyperoxaluria may occur as a result of excessive dietary intake, because of malabsorption and/or steatorrhea (enteric hyperoxaluria) or because of an inborn error of metabolism (primary hyperoxaluria).

Enteric hyperoxaluria commonly occurs in association with inflammatory bowel diseases and may contribute to an increased incidence of stone formation in such patients.[457] Fat malabsorption contributes to the formation of calcium soaps, increasing the enteric concentration of unbound oxalate that is absorbed through the damaged bowel wall. Primary hyperoxaluria may be type 1 (glycolic aciduria) or type 2 (L-glyceric aciduria). Patients with type 1 disease present in the first decade of life with recurrent calcium oxalate nephrolithiasis. Inheritance is autosomal recessive and survival is poor. Type 2 disease is rarer and has been claimed to run a milder course, despite the passage of similarly high concentrations of urinary oxalate. The urinary excretion of oxalate may increase to 61.4 mg/day (700 μmol/day) when a diet containing an excess of oxalate-rich foods is taken and to as much as 263 mg/day (3 mmol/day) in patients with primary hyperoxaluria.

Ideally, urine for oxalate analysis should be collected into acid to prevent the crystallization of calcium oxalate crystals. This also prevents ex vivo formation of oxalate from ascorbate, a cause of factitious hyperoxaluria in individuals ingesting excessive amounts of vitamin C. A number of approaches to the measurement of urinary oxalate have been employed including high-performance liquid chromatography (HPLC), enzymatic and capillary electrophoretic methods.[159,171,233,327] The enzymatic methods employ the enzyme oxalate oxidase (EC 1.2.3.4. oxalate:oxygen oxidoreductase). With this method, the sample of urine is initially acidified to pH 1.8 (typically with 2 mmol/L HCl) to ensure complete solubilization of any calcium oxalate crystals. The oxalate is oxidized to carbon dioxide and hydrogen peroxide by oxalate oxidase, and the hydrogen peroxide is detected with horseradish peroxidase and coupled with an oxygen acceptor reagent such as 3-dimethyl aminobenzoic acid and 3-methyl-2-benzothiazolinone hydrazone to yield an indamine dye that absorbs at 590 nm. Laker and colleagues[230] have proposed a charcoal column pretreatment step to remove interferents from the urine. Petrarulo and colleagues[327] did not find this necessary. In addition, they found the method could also be used for deproteinized plasma samples. An alternative approach to the detection of hydrogen peroxide using catalase has also been described.[159] The oxalate oxidase is specific for oxalate; however, the peroxide detection reaction may suffer from interferences (e.g., turbidity in the catalase-mediated reaction, ascorbic acid, and other reducing agents in the peroxidase-mediated reaction). The choice of oxygen acceptor will determine the potential for interference from species, such as ascorbic acid.

A dietary history is important in the evaluation of calcium oxalate stone formers. Patients who are excreting

large amounts of oxalate may be offered dietary advice to modify their risk of future stone formation. Foods rich in oxalate include beets, tea, spinach, sorrel, wheat bran, strawberries, rhubarb, black currants, peanuts, and chocolate.[365,413,452] Paradoxically, epidemiological evidence has actually demonstrated a protective effect of high tea consumption.[78] This has been attributed to the low bio-availability of oxalate in tea and the inhibition of tubular ADH action by caffeine. Patients may also be treated with calcium carbonate, which binds oxalate in the gut, rendering it unavailable for absorption. Alternatively, pyridoxine (vitamin B_6) may be used; this increases the catabolism of oxalate to more soluble products.[452] It should be remembered that the use of calcium-lowering diets, once favored in the treatment of calcium stone formers, increases intestinal absorption of oxalate.

Citrate

Urinary citrate inhibits stone formation by forming soluble complexes with calcium. It is present in the diet in many fruits. Excretion (typically between 116 and 926 mg/24 hours [0.6 and 4.8 mmol/24 hours] for adult males and 250 and 1160 mg/24 hours [1.3 and 6.0 mmol/24 hours] for adult females)[365] is reduced in the calcium stone–forming population.[412] Urinary citrate measurement may be of value in the assessment of stone-forming risk, particularly in the setting of distal renal tubular acidosis where the reduction in filtered bicarbonate appears to increase tubular reabsorption of citrate with consequent hypocitraturia.[147] Inadequate urinary acidification compounds the increased risk of calcium stone formation. Treatment with carbonic anhydrase inhibitors (e.g., acetazolamide[312] and topiramate[197]) mimics distal renal tubular acidosis with consequent increase in stone risk. Hypocitraturia may also be seen in malabsorption and urinary tract infection. Administration of oral alkaline citrate increases urinary citrate concentration by increasing the pH of tubular cells. It has been shown to be effective in the treatment of nephrolithiasis,[313,413] although there are side effects and compliance is poor.

Citrate is measured by gas chromatography, capillary electrophoresis,[171] or an enzyme-mediated reaction.[283] While methods using aconitase (EC 4.2.1.3) and isocitrate dehydrogenase (EC 1.1.1.42), or citrate lyase (EC 4.1.3.6) and oxaloacetate decarboxylase (EC 4.1.1.3), have been described, a method using the lyase together with malate dehydrogenase (EC 1.1.1.37) and lactate dehydrogenase (EC 1.1.1.27) is preferred. The combination of the two dehydrogenase pathways has been proposed to ensure that any oxaloacetate ion enzymatically decarboxylated is also measured. The enzyme-mediated decarboxylase pathway is less favored because of the poor stability of the enzyme. Using a reaction sequence that involves incubation of the sample with all constituents except the citrate lyase ensures that all endogenous oxaloacetate and pyruvate are removed. Analysis of serum involves a deproteinization step, while urine should be titrated to pH 8.0 before analysis. A typical incubation period is 10 to 15 minutes, and the citrate can be quantitated from the decrease in the absorbance at 340 nm.[283] A cheap, rapid, automated adaptation of this procedure, which does not require a deproteinizing step, has been described.[28]

Struvite Stones

Struvite stones (also called triple phosphate or infection stones) are composed of magnesium ammonium phosphate hexahydrate. The formation of such stones requires urinary tract infection with urea splitting organisms and such stones are therefore more common in females and in certain patient populations (e.g., paraplegics).[365] The risk of progression to CKD appears higher in patients who develop infection stones than in other forms of stone disease.[122]

Cystinuria

Cystinuria is an autosomal recessive condition in which there is excessive urinary excretion of cystine because of a defect in proximal renal tubular reabsorption. In the most common form of the disease there is also excess excretion of the dibasic amino acids (lysine, ornithine, and arginine). These share the same renal tubular transporter although their presence in excess in urine appears benign. More rarely, isolated cystinuria is seen. The reader should note that cystinuria should not be confused with cystinosis, which is a condition associated with intracellular accumulation of cystine but not excess urinary excretion of cystine.

The normal urinary excretion of cystine has been reported to be 4.81 to 48.1 mg/24 hours (40 to 400 µmol/24 hours).[365] Its relatively low limit of solubility, 18.0 mg/dL (1500 µmol/L),[452] is exceeded in many patients with cystinuria,[365] resulting in the formation of hexagonal crystals and, ultimately, cystine stones. Cystine stones are usually only seen in homozygotes, although there is some evidence that heterozygotes are at increased risk of stone formation.[128] Cystinuria may present at any age from infancy to old age, although presentation is most common in the second and third decades.

The finding of a cystine stone should prompt confirmation of cystinuria by urinary analysis.[365] It could be argued, however, that all stone formers should be screened for cystinuria; at least 10% of cystinurics form stones in which cystine cannot be detected, presumably because of epitaxis.[281] The index of suspicion should be increased in patients who are relatively young stone formers and in those with a positive family history. Once a cystinuric patient is diagnosed, it is important to screen all members of the family, particularly to detect affected siblings.

Cystine can be measured in urine using the cyanide-nitroprusside test,[45] thin layer chromatography, by quantitative amino acid analysis using either ion exchange or liquid chromatographic techniques[382] or mass spectrometry. In the cyanide-nitroprusside test, cystine is split into two molecules of cysteine by cyanide. Sodium nitroprusside reacts with the free sulfide groups to give a magenta color. The test is

hazardous and will give false-negative results in acidified or infected urines, in patients receiving penicillamine therapy, or if the sodium nitroprusside solution is not fresh. Further, it cannot distinguish between cystine and homocystine or between heterozygote and homozygote cystinurics. It is not useful when monitoring the treatment of known cystinurics, who require quantitation of their urinary cystine output or concentration. In practice, amino acid analysis allows simultaneous quantitation of the dibasic amino acids, which may be helpful for characterizing the clinical phenotype.[382] Quantitative amino acid analysis is described in Chapter 20.

Treatment of cystinuria is aimed at maintaining cystine below its saturation point by maintaining high fluid intake, particularly at night. Other treatments include urinary alkalinization (cystine is more soluble in alkaline urine) and chelation with D-penicillamine. Quantitative analysis is an important adjunct for monitoring penicillamine therapy, which can be optimized on the basis of the free cystine versus cystine/penicillamine disulfide. Penicillamine itself may cause glomerular damage and thus regular monitoring of urinary protein excretion is also recommended.

Prostaglandins and NSAIDs in Kidney Disease

The prostaglandins are a series of C_{20} unsaturated fatty acid derivatives of cyclo-oxygenase (COX) on cell membrane arachidonic acid (see Chapter 26). The major renal vasodilatory prostaglandin is PGE_2, which is synthesized predominantly in the medulla. The major vasoconstrictor prostaglandin is thromboxane A_2, which is produced primarily within the renal cortex.[91] PGE_2 increases renal blood flow rate, inhibits sodium reabsorption in the distal nephron and collecting duct, and stimulates renin release.[91] These actions promote natriuresis and diuresis. In patients with CKD, renal PGE_2 excretion rates are 3 to 5 times higher than those in healthy subjects and therefore PGE_2 production represents a compensatory response to loss of nephron mass.[414] Vasodilatory prostaglandins are synthesized following stimulation with renal sympathetic adrenergic and AII-dependent mechanisms to offset or modulate vasoconstriction.[275] In the tubule, prostaglandins act as autocoids, exerting their effects locally, near the site of synthesis.

NSAIDs block the synthesis of COX products of arachidonic acid, which have a critical role in renal hemodynamics, control of tubular function, and renin release. It is now apparent that two isoforms of COX synthesize prostaglandins. COX-1 is a resident or constitutive form and COX-2 is an inducible form that increases with disorders of inflammation.[381] NSAIDs are nonspecific inhibitors of both COX isoforms. Analgesic nephropathy is a common cause of ESRD in a number of countries, reaching 10% in Switzerland and Australia, but is essentially a preventable condition for which biochemical monitoring has proved useful. The incidence of this disease has decreased over the last decade as awareness has improved and phenacetin was withdrawn from over-the-counter analgesic mixtures. In the United States, 1 in 5 citizens (50 million) report that they use an NSAID for an acute complaint.[448] Young healthy individuals tolerate NSAIDs well. However, older people demonstrate significant reduction of GFR within 1 week of ingestion of NSAIDs.[142] Renal blood flow, particularly within the medulla, is dependent on systemic and local production of vasodilatory prostaglandins, and analgesic-related kidney damage is seen mostly within the medulla, with late changes causing papillary necrosis and interstitial fibrosis. Hyperkalemia can develop either as a consequence of reduced GFR or secondary to hyporeninemic hypoaldosteronism.

In normal rat and dog kidney COX-2 is sparsely expressed in the macula densa, but expression is upregulated when animals are volume depleted.[152] Selective COX-2 inhibitors have been discovered but it is not known what the effects of these drugs will be on renal homeostasis. Acute interstitial nephritis has been described with COX-2 inhibitors.[160,264]

Monoclonal Light Chains and Kidney Disease

Immunoglobulin (Ig) molecules are formed in secretory B cells from polypeptide heavy (H) and light (L) chains. Disulfide bonds covalently assemble the chains. Each chain has a constant and a variable region. The heavy chains α, β, γ, δ, and ε denominate the antibody isotype and light chains include peptide molecules that are called kappa (κ) and lambda (λ). A complete Ig molecule will contain either κ or λ. The proportion of Ig containing κ versus λ is 3:2 in humans. The molecular weight of light chains is around 22.5 kDa (see Chapters 9 and 20). An excess production of light over heavy chains appears to be required for efficient Ig synthesis, resulting in the release of free light chains into the circulation. In normal individuals, the small quantity of circulating polyclonal light chains is filtered by the glomerulus and around 90% reabsorbed in the proximal tubule. The binding sites on the brush border of proximal tubule cells exhibit relative selectivity for light chains compared with albumin and lactoglobulin.[18] Light chains are then degraded by proteases and returned to the circulation. When the concentration of filtered light chains is increased, this leads to alteration in the proximal tubule cells, including prominent cytoplasmic vacuolation, loss of microvillus border, and epithelial cell exfoliation.[366]

There is evidence that light chains are directly pathogenic. The pattern of human renal injury associated with monoclonal light chains can be reproduced in mice injected intraperitoneally with large amounts of light chains isolated from patients with myeloma or light chain–associated amyloid (AL-amyloid).[223] In a rat model of multiple myeloma, spontaneously developing light chain–synthesizing tumors were transplanted to normal animals that subsequently developed crystalloid formations within phagolysosomes in proximal tubule cells.[396] Light chains can deposit in the kidney as casts, fibrils, and precipitates or crystals, giving rise to a spectrum of disease including cast nephropathy, amyloid, light chain deposition disease (LCDD), and the Fanconi syndrome. However, not all patients with a large excess production of monoclonal light chains develop

disease. Other promoters including dehydration, hypercalcemia, contrast medium, and NSAIDs have been implicated.

Myeloma or multiple myeloma is a neoplastic proliferation of secretory B cells (plasma cells) that produce excess amounts of a monoclonal Ig (paraprotein), so-called M protein because of the characteristic peaks obtained from serum protein electrophoresis on agarose gel. This clonal production is associated with either an excess or pure light chain production. In multiple myeloma complete monoclonal Igs (usually IgG or IgA) are accompanied in the plasma by variable concentrations of free light chains that appear in the urine as Bence Jones proteins. Henry Bence Jones in London first described these in 1848. M proteins and light chains can be identified in the blood and/or the urine in 98% of patients with myeloma using protein electrophoresis and immunofixation. Immuneparesis, with reduction in nonparaprotein Ig, is characteristic of myeloma. The nephrotoxic potential of Bence Jones proteins has been demonstrated in elegant experiments on animal models.[397]

The incidence of myeloma is 40 new cases per million population per year.[456] Myeloma is more common in men than women and the median age at presentation is 65 years.[226] Impairment of kidney function at presentation occurs in almost 50% of patients.[85,456] Although most recover following treatment of other factors contributing to renal impairment (e.g., dehydration, hypercalcemia, infection, and nephrotoxic drugs) about 10% have severe renal involvement caused by the effects of light chains on the kidney. Severe kidney failure may be caused in myeloma following deposition of light chains within tubules in association with THG, so-called cast nephropathy (myeloma kidney). Cast nephropathy can present acutely, again precipitated by dehydration, hypercalcemia, or NSAIDs, or "de novo" in the absence of these factors. It occurs when the reabsorptive capacity of proximal tubule cells is exceeded by overproduction of light chains. In myeloma, light chain excretion can exceed 20 g/day. Casts are large and numerous and predominantly found in the distal convoluted tubule and collecting ducts, causing obstruction to urine flow. They have a hard and fractured appearance with lamination visible on histological examination of kidney biopsy specimens. Immunofluorescence confirms that casts are composed of monoclonal light chains and THG. Casts are usually stained exclusively with either anti-κ or anti-λ antibodies. At biopsy there is often an interstitial inflammatory infiltrate, and fibrosis and tubular atrophy can be extensive. Not all light chains induce cast formation. The ability of light chains to form casts is based on binding to THG, a highly glycosylated and acidic protein.[358] Light chains interfere with proximal tubule cell function and this increases delivery to the distal tubule. A specific binding site for light chains has been identified on THG, and light chains with high affinity appear to be more likely to produce obstructing intratubular casts.[178] Physico-chemical determinants of binding of light chains to THG include the isoelectric point (pI) of the light chain. Those molecules with a pI above 5.1 (above the tubular fluid pH in the distal nephron) will have a net positive charge that may promote binding via charge interaction to anionic THG (pI 3.2). Urinary alkalinization reduces binding of light chains to THG in animal models.[170] Nephrotoxicity may be determined by the ability of light chains to self-associate, leading to the formation of high molecular weight aggregates that are more likely to deposit in tissues, particularly in the setting of volume depletion.

The clinical features of myeloma include a normochromic normocytic anemia, bone pain with pathological fractures (back or chest rather than extremities), and hypercalcemia in 20% of patients. Severe kidney failure may dominate the clinical picture and 84% of patients studied retrospectively with severe renal impairment required dialysis.[183] Only 15% of these patients regained independent kidney function. Treatment has two main objectives: therapy is targeted at predisposing factors for cast nephropathy as indicated and chemotherapy is used to reduce the production of monoclonal antibodies and light chains from monoclonal plasma cells. Supportive therapy includes increased fluid intake where permissible to 3 L/day, treatment of hypercalcemia, treatment of infection, and withdrawal of NSAIDs. Anemia can be addressed by replacement with blood products or the use of epoetins. Epoetin has been demonstrated to be efficacious in a placebo-controlled study of 145 patients.[80] Skeletal complications are common in myeloma and pathological fractures occur in the setting of apparently trivial injury. There is increased osteoclastic activity mediated by interleukin (IL)-1, IL-6, TNF, and macrophage inflammatory protein-1α.[148] Biphosphonates are specific inhibitors of osteoclastic activity and have beneficial effects in myeloma.[21] Biphosphonates may exert direct antitumor effects on myeloma since they induce significant expansion of γδ-T cells in peripheral blood mononuclear cells, which exhibit specific cytotoxicity against myeloma cell lines in vitro.[225]

Chemotherapy can be considered as part of the urgent treatment for patients with kidney involvement in myeloma. The aim is to reduce the concentration of free light chains. Chemotherapy with alkylating agents such as melphalan, and combination treatment with cytotoxic agents and dexamethasone are the preferred initial treatment regimens and doses and schedules are adjusted depending on the level of GFR. Combination chemotherapy results in partial responses but only rarely complete remission.[3,137,256] Autologous bone marrow transplantation can be considered in some cases.[7] Estimated 5-year survival following bone marrow transplantation in one series of 200 patients was 52% compared with 12% in those patients treated with combined chemotherapy alone.

Poor prognostic features in myeloma include increased β_2-microglobulin, C-reactive protein, and lactate dehydrogenase (LD), and abnormal cytogenetics (especially deletion of 13q). Refractory disease is associated with a short survival, and treatment options include further chemotherapy and a

trial of the antiangiogenesis compound thalidomide.[307,391] The rationale for thalidomide comes from the observations that prominent bone marrow vascularization occurs in myeloma and correlates with markers of poor prognosis, and that plasma levels of angiogenic cytokines are elevated in myeloma. Clinical trials of thalidomide in myeloma were first described in 1965 and more recent trials show some promise in terms of reduction of paraprotein load and 1-year survival.[391,463]

In addition to chemotherapy, plasma exchange is often used in the treatment of myeloma cast nephropathy to acutely reduce free light chain load. There is a paucity of trial data,[191,473] but one prospective study of 29 patients demonstrated an increased 1-year survival following plasma exchange treatment. However, several early deaths in the control group render the data difficult to interpret.[473] A further study of 21 patients with myeloma and ARF demonstrated advantages of plasma exchange in patients with kidney failure severe enough to require dialysis.[191] The United Kingdom Renal Association and the United Kingdom Myeloma Forum are currently recruiting almost 300 patients to a national study of plasma exchange in myeloma cast nephropathy (Myeloma Renal Impairment Trial-MERIT).

In cast nephropathy, there is glomerular filtration of *intact* light chains. Excess production of monoclonal light chains (or rarely heavy chains) can cause disorders in which *fragments* are deposited in the kidney and other tissues: AL-amyloid, LC- and HC-deposition diseases (LCDD and HCDD). The diagnosis of AL-amyloid can be suspected from the clinical findings of heavy proteinuria and serum or urinary paraprotein. However, 10% to 15% of patients with primary amyloid do not have a detectable serum or urinary paraprotein. The demonstration of a clonal excess of plasma cells on bone marrow biopsy may help with the diagnosis in those without detectable paraprotein. In AL-amyloid, fibrils derived from the variable region of light chains are deposited in the tissue. Seventy-five percent are derived from the λ-light chain. Since it is the variable region that is deposited, it is often difficult to assess with immune reactants. Only 50% of AL-amyloid cases are stainable with commercially available antisera to κ and λ. The deposits are fibrillar in nature and bind to Congo red. Amyloid fibrils also bind to serum amyloid P (SAP) component, allowing noninvasive evaluation by radiolabeled SAP scanning.[155]

The deposits in LCDD are usually composed of κ-light chains. They are granular and do not bind to Congo red, thioflavine-T, or SAP. The constant region of the light chain is typically deposited in this disorder and therefore immunostaining is strongly positive. These conditions may be associated with myeloma and other conditions leading to overproduction of monoclonal light chains, such as lymphoma. Both AL-amyloid and LCDD have a poor prognosis and the mean survival is 18 months, with 50% of patients dying from cardiac failure. Treatment options are unsatisfactory, although prednisolone and melphalan may be tried.[227,228,393] Circulating free light chains can be detected in most patients with AL-amyloid and patient outcome following treatment is improved if the concentration of free light chains can be reduced by 50%.[229]

The French Myeloma Group has published results of bone marrow or stem cell transplantation in AL-amyloid.[285] In a retrospective analysis of 21 patients treated with melphalan and stem cell transplantation, 43% died within 1 month and the remainder had a favorable outcome.

Light chains may cause tubular dysfunction, especially of the proximal tubular cells. Characteristically the light chain variable domain is resistant to degradation by proteases in lysosomes in the tubular cells. The variable domain fragments accumulate in proximal tubular cells, and clinical features include RTA and phosphate wasting.

Assessment of Renal Concentrating Ability: Urinary Osmolality

Urinary concentration can be quantified either by measuring specific gravity (see Chapter 24) or by measuring urinary osmolality. For most clinical purposes, measuring specific gravity is probably sufficient,[322] but urinary osmolality measurement is critical to the diagnosis and differential diagnosis of DI using the water deprivation test.

The urinary osmolality of normal individuals may vary widely, depending on the state of hydration. After excessive intake of fluids, for example, the osmotic concentration may fall as low as 50 mOsm/kg/H_2O, whereas in individuals with severely restricted fluid intake, concentrations of up to 1400 mOsm/kg/H_2O can be observed. In individuals on an average fluid intake, values of 300 to 900 mOsm/kg/H_2O are typically seen. If a random urine specimen of a patient has an osmolality of >600 mOsm/kg/H_2O (or >850 mOsm/kg/H_2O after 12 hours of fluid restriction), it can generally be assumed that the renal concentrating ability is normal.

In chronic progressive kidney disease, the concentrating ability of the tubules is diminished and in acute tubular necrosis the urinary osmolality, if there is urine output at all, approaches that of the glomerular filtrate.

For a discussion on the measurement of the urinary and plasma osmolality, readers are referred to Chapters 27 and 34.

RENAL REPLACEMENT THERAPY

RRT includes dialysis procedures such as HD, PD, continuous hemofiltration (HF), and continuous hemodiafiltration (HDF). These techniques are used to temporarily or permanently remove toxic substances from the blood when the kidneys cannot satisfactorily remove them from the circulation. In addition, kidney transplantation has also become an effective form of RRT. Extensive laboratory support is required by an RRT program (Table 45-12).

TABLE 45-12 Laboratory Support for Renal Replacement Therapy

Complications	Laboratory Tests
Acute	
Dialysis disequilibrium	Plasma electrolytes
Pyrexia	C-reactive protein
Bleeding	Clotting factors
Chronic	
Anemia	Hemoglobin, ferritin
Septicemia/peritonitis	C-reactive protein Culture and sensitivity
Malnutrition	Albumin, prealbumin
Cardiovascular disease	Lipid profiles
Amyloidosis	Serum β_2-microglobulin
Osteodystrophy	Ca^{2+}, PO^{-4}, bone alkaline phosphatase, intact PTH, aluminum
Adequacy of Dialysis	
Urea kinetic modeling (URR)	Predialysis and postdialysis urea
Weekly creatinine clearances	Predialysis and postdialysis creatinine
Peritoneal equilibration test (PET)	Plasma and dialysate creatine and glucose
Transplant Monitoring	
Immunosuppression	Trough or 2-hr whole blood cyclosporin A concentration Trough whole blood tacrolimus and rapamycin concentrations
Graft function	Serum creatinine, plasma, and urine electrolytes

BACKGROUND

In 1861, Thomas Graham Bell in Glasgow, Scotland, carried out the first dialysis experiments (and coined the term "dialysis"), separating crystalloids and colloids in a solution. Bell predicted that this technique could have medical application, but this was not realized until nearly 100 years later in the work of Willem Kolff and then Belding Scribner, who made HD a feasible treatment in the early 1960s. Since then, HD and more recently PD have extended the lives of many people, sometimes for up to 20 or 30 years.

DIALYSIS

Dialysis is the process of separating macromolecules from ions and low molecular weight compounds in solution by the difference in their rates of diffusion through a semipermeable membrane, through which crystalloids can pass readily but colloids pass very slowly or not at all. Two distinct physical processes are involved: diffusion and ultrafiltration (UF).[93]

The timing of initiation of dialysis treatment is controversial. There is debate as to whether early initiation of dialysis improves outcomes over late starters.[37,222,416] The K/DOQI 2000 Update Clinical Practice Guidelines suggest that dialysis should be started when kidney function drops below a GFR of 10.5 ml/min/1.73 m^2.[294] This is higher than the typical level in the United Kingdom. A 2002 study from Glasgow, Scotland, found no significant benefit in patient survival from earlier initiation of dialysis.[416] The calculated GFR at the beginning of dialysis was 8.3 mL/min.

Hemodialysis and Hemofiltration

HD is the most common method used to treat advanced and permanent kidney failure. Clinically, it is considered the default therapy that is utilized in the increasing numbers of patients unsuitable for other modalities of PD and kidney transplantation. Operationally, it involves connecting the patient to a hemodialyzer into which their blood flows. After filtration to remove the wastes and extra fluids, the cleansed blood is returned to the patient. It is still a complicated and inconvenient therapy requiring a coordinated effort from a healthcare team that includes the patient, nephrologist, dialysis nurse, dialysis technician, dietitian, and others.

Description

HD utilizes diffusive and convective mass transfer across a semipermeable membrane. The driving force for diffusion is the concentration gradient between blood and dialysate. Smaller solutes with larger concentration gradients give increased diffusion. The concentration gradient is maintained by using countercurrent flows and high flow rates. Heparinized blood is pumped in one direction across the membrane and the recipient fluid, the dialysate, flows at a rate of 5 to 600 mL/min in the opposite direction. Water molecules and small molecular weight molecules can cross the membrane, while larger proteins and cellular elements are retained in the vascular space. Convection is the bulk movement of solvent and dissolved solute across the membrane, down a transmembrane hydrostatic pressure gradient.

HD relies on good vascular access to the circulation of the patient to enable blood to be pumped around the extracorporeal circuit at a rate in excess of 300 mL per minute. This ability was not introduced until the 1960s. Although Kolff in Groningen Hospital in the Netherlands performed the first dialysis experiments in humans in 1943, the problem of dialysis support with long-term vascular access was not solved until Scribner developed the arteriovenous cannula in 1960. This was followed by the development of the surgically

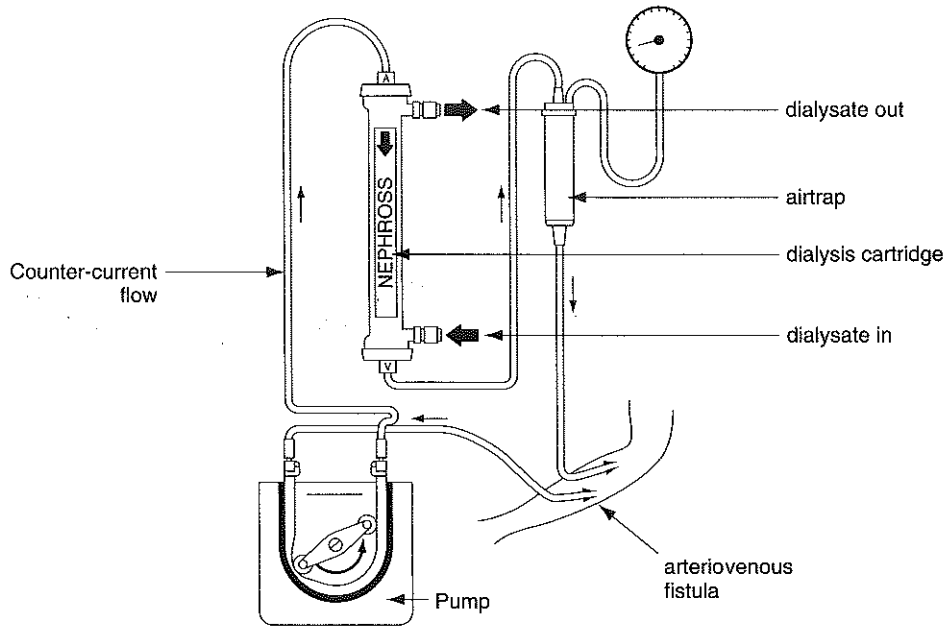

Figure 45-17 A hemodialyzer setup with inset flow diagram.

created arteriovenous fistula (AVF), introduced by Brescia and co-workers in 1966, which provided permanent vascular access. The Dialysis Outcomes Practice Patterns Study (DOPPS) has confirmed a wide variation in how dialysis is achieved throughout the world. For example, the majority of patients in Germany have an AVF as their main access, whereas in the United States a fistula is used for access in less than 30% of cases.[329] When used as a patient's first access, AVF survival is considered superior to arteriovenous grafts regarding time to first failure, and AVF survival is longer in Europe compared with the United States.

An example of a hemodialyzer is shown in Figure 45-17. The most important functional part is the dialyzer membrane. Biocompatibility of the dialyzer membrane is an essential requirement because of high surface areas and long contact times with blood. The most important physiological interactions that occur, apart from protein fouling of tubing and membranes, are complement activation and induction of cytokine release.

A variety of membranes are available with different surface areas and filtration characteristics. The oldest type of membrane was made from cuprophane and cellulose acetate; however, these have been replaced by more biocompatible synthetic membranes made from polysulfone and polyacrylonitrile. Biocompatible membranes are more rigid (allowing higher flow rates) and have higher clearances of larger molecules, such as β_2-microglobulin. By altering the applied pressure across the membrane, fluid removal by UF can be regulated, and by altering the flow rate of dialysate and blood, solute removal can be regulated. Patients are dialyzed in home-based or hospital-based units, with dialysis usually performed three times a week for sessions lasting between 3 and 5 hours. This dialysis schedule is largely empirical insofar as it reconciles adequate treatment with breaks between treatments to provide the patient with a reasonable quality of life. Approaches to increase the dose of dialysis have been explored. These include short daily HD that entails a 2- to 3-hour dialysis on 6 days per week.[271] Alternatively, slow overnight dialysis for 5 to 7 nights has been employed. These regimens have been reported to improve outcome.[271,343,420]

Conventional HD uses low-flux dialyzers, allowing diffusive but little convective solute removal. Middle molecule clearance is poor. HF is a convective treatment. Although middle molecule clearances are improved, small molecule clearance is poor. HF is used for continuous treatment in Intensive Care Units in the management of ARF. High-flux HD using biocompatible membranes allows convective and diffusive solute removal. The use of very pure water is crucial in high-flux modes, because dialysis fluid is infused directly into the bloodstream by back filtration. The Hemodialysis (HEMO) Study, a randomized clinical trial designed to determine whether increasing the dose of dialysis or using a high-flux dialyzer membrane alters major outcomes concluded that patients undergoing HD thrice weekly had no major benefit from a higher dialysis dose than that recommended by current United States guidelines or from the use of a high-flux membrane.[98]

HDF is HD in which fluid removal exceeds the desired weight loss, and fluid balance is maintained by the infusion of a sterile pyrogen-free solution. This technique offers the advantages of both HD and HF in a single therapy. The replacement fluid, previously supplied in autoclaved bags, is now generated "online" from concentrated bicarbonate and

uses 20 to 30 L of water per session.[234] The result is that HDF provides 10% to 15% increase in urea clearance compared with HD and increased middle molecule clearances. Water for online preparation of substitution solution should meet common standards for dialysis water regarding chemical contaminants, but have a higher quality regarding microbiological contaminants. It should be practically free from bacteria and pyrogens (i.e., ultrapure). Dialysis water is purified using a combination of techniques, including softening and deionization, carbon adsorption, dual-pass reverse osmosis, and ultraviolet irradiation. Online HDF has been used extensively on continental Europe over the past 15 years or so. Bicarbonate is now favored over acetate as the buffer of choice in HD since it is associated with a reduction of intradialytic symptoms.

Assessment of Adequacy of Hemodialysis

The assessment of adequacy of dialysis treatment for individual patients in the clinical setting includes consideration of the patient's well-being, cardiovascular risk, nutritional status, and degree of achievable ultrafiltration. It also includes estimates of a number of laboratory parameters—such as hemoglobin, phosphate, and albumin—and clearance of the small solutes urea and creatinine. During the following discussion, the term "adequacy" will refer to small solute clearances obtained from both dialysis and residual renal function (RRF). For practical reasons, HD adequacy is calculated using urea as the small solute.

Urea kinetic modeling (UKM) is used to assess adequacy. The kinetics of urea removal during dialysis and the interdialytic regeneration of urea sessions are modeled using computer software such as Adequest (Baxter Laboratories, Deerfield, IL). The computer modeling considers duration of dialysis, RRF, total clearance predicted from the dialyzer, blood and dialysate flow rates, and fluid removal during dialysis.[132] The software then calculates K_t/V urea and protein catabolic rate. The K_t/V (defined in Table 45-13) is now the most commonly used assessment of the adequacy of dialysis. The only analytical measurements required are predialysis and postdialysis urea, duration of dialysis, and weight loss during dialysis. This technique has become more sophisticated with the development of online clearance monitoring based on conductivity variation.[224]

In practice, rather than using full UKM, the simplest calculation is the urea reduction ratio (URR). The percentage fall in plasma urea attained during a dialysis session is measured as follows:

$$\frac{\text{Predialysis [urea]} - \text{Postdialysis [urea]}}{\text{Predialysis [urea]}} \times 100\%$$

The URR does not take convective removal of urea or RRF into account. Its accuracy is lower than K_t/V measured by formal UKM, particularly at high values of URR and K_t/V.[388] Observational studies in populations of dialysis patients have shown that variations in URR are associated with major differences in mortality.[310]

TABLE 45-13 Assessment of Dialysis Adequacy

1. Urea reduction ratio (URR) = (predialysis-postdialysis urea/predialysis urea) × 100 should be >60% if dialysis is adequate.

K_t/V = †total urea clearance/distribution volume:

$$C_t = C_0 \times e^{(-K_t/V)}$$

where

K = urea clearance
t = time of dialysis
V = volume of urea distribution
C_t = postdialysis urea
C_0 = predialysis urea

Some methods assume a constant relationship between V and body weight, which is not necessarily true in uremia.

2. Relative mortality risk for peritoneal dialysis patients (CANUSA study):

Variable	Relative Risk	
Age	1.03	For each year older
Diabetes	1.45	If present
Cardiovascular disease	2.09	If present
K_t/V	0.94	For each extra 0.1/wk
Creatinine clearance	0.93	For each extra 5 L/wk

In general, the minimum standard for HD three times a week is a K_t/V of 1.0 to 1.4. The K_t/V effectively describes the power of the dialysis session. A retrospective analysis of the National Cooperative Dialysis Study (NCDS) was the first study to identify a threshold in level of K_t/V and outcomes in HD.[252] There are several assumptions associated with the use of UKM including: (1) urea is considered to be uniformly distributed in total body water in a thoroughly mixed single pool; (2) urea is continually added to the pool by protein metabolism at a constant rate; and (3) urea is removed continuously by RRF and intermittently by dialysis following a first-order process of elimination dependent upon plasma concentration. A variety of formulas are used to calculate K_t/V, which makes the comparison of results from different institutions difficult; differences for one measurement can be as wide as 0.98 to 1.43.

Peritoneal Dialysis

Peritoneal dialysis (PD) is a type of dialysis in which dialysate is injected into the patient's peritoneal cavity with the peritoneum then employed as the dialysis membrane. It was first explored by Ganter in 1923 and initially showed poor results. The modern era of PD started in 1953, with intermittent

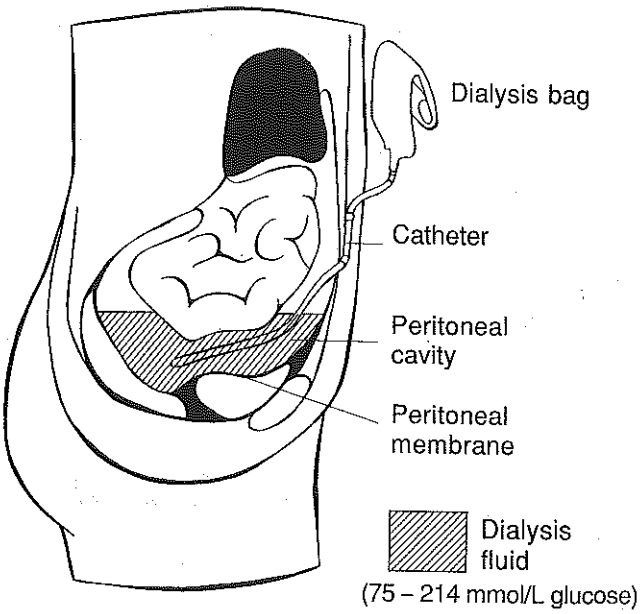

Figure 45-18 Diagrammatic sketch of peritoneal dialysis. *(Redrawn from Nolph KD. Peritoneal Anatomy and Transport Physiology. In: Maher JF, ed. Replacement of renal function by dialysis, 3rd ed. Kluwer Academic Publishers/Springer: Dordrecht, The Netherlands 1989:Chapter 23.)* To convert glucose concentration in mmol/L to mg/dL, multiply by 18.

irrigation of the peritoneal cavity with commercially prepared solutions and access achieved through a single disposable catheter (Figure 45-18). Popovich and co-workers in 1976 introduced the concept of portable equipment, and this approach developed into continuous ambulatory peritoneal dialysis (CAPD)[31]; a type of PD performed in ambulatory patients during normal activities. The percentage of incident and prevalent patients receiving PD has declined in the United States over recent years, particularly in older people. For example, between 8% to 10% of dialysis patients were treated with PD in United States in 2002.[427] Use of PD varies between countries depending on access to HD. For example, in the United Kingdom 31% of prevalent patients receive PD[425] and in Mexico 90% of patients receive PD.[318]

Description

Operationally, CAPD uses the patient's own peritoneal membrane (surface area approximately $2\,m^2$) across which fluid and solutes are exchanged between the peritoneal capillary blood and the dialysis solution placed in the peritoneal cavity. Fluid removal (UF) is achieved by using dialysis fluids containing high concentrations of dextrose acting as an osmotic agent; as the dextrose passes across the peritoneal membrane, the rate of fluid removal decreases. Conventional therapies use four daily exchanges of approximately 2 L of fluid with approximately 10 L of spent dialysate generated, including UF. RRF is critical to the success of PD since only a few milliliters per minute can contribute substantially to urea clearance and C_{Cr}, with each additional milliliter resulting in an extra 10 L of clearance per week. Practical reasons for opting for PD include (1) preservation of RRF and vascular access sites, (2) increased patient autonomy, (3) flexibility as to where the treatment can be administered, and (4) ease of self-treatment, with lower capital costs involved. The higher permeability of the peritoneal membrane provides good removal of β_2-microglobulin and may help to protect patients on PD from the development of dialysis-related amyloid. Blood pressure control and extremes of fluid shifts are not so problematic as those that occur on intermittent HD.

Automated PD (APD) is now widely available. This requires a programmable machine to regulate flow, dwell time, and drainage, and it may be performed at night. Solute clearance can be increased by leaving fluid in the peritoneum during the day and by performing an additional daytime exchange.

The main disadvantage with PD is the risk of infection causing peritonitis. Incidence rates of peritonitis have decreased over the years and the current standard from the United Kingdom Renal Association is that the peritonitis rate should be less than 1 episode per 18 patient months.[422] The immediate effect of peritonitis is to reduce UF, and repeated episodes can cause scarring and fibrosis with permanent loss of filtration. Icodextrin, a nonglucose polymer, may have some value in improving UF in patients with loss of peritoneal function. However, loss of UF in the setting of loss of RRF usually requires transfer of dialysis modality to HD.

Assessment of Adequacy in PD

A series of clinical outcome reports have demonstrated that measures of PD solute removal correlate with patient status and outcome.[231,261,384] In particular, a multicenter prospective cohort study of 680 incident CAPD patients [Canada-United States (CANUSA) Study] showed that a decrease of 0.1 in weekly urea clearance (defined by K_t/V_{urea}) was associated with a 5% increase in the relative risk of death.[71] Similarly a decrease of $5\,L/wk/1.73\,m^2$ of total creatinine clearance (C_{Cr}) was associated with a 7% increase in the risk for death. As a consequence of these studies, national guidelines from the United Kingdom,[422] Australia,[59] and the United States[294] have set standards of dialysis adequacy in terms of small solute removal. An estimate of adequacy is performed in all patients within 6 to 8 weeks of commencement of dialysis. Further studies should be performed at least annually.[422]

The role of solute removal in defining adequacy of PD is complicated by the concern that solute removal by PD may not be clinically equivalent to an equal quantitated solute removal by RRF.[90] For PD, small solute clearance targets have often been established on the assumption that peritoneal and renal clearances are equivalent and therefore additive. However, most studies that examined the relationship between small solute clearances and mortality rates noted that patient survival was directly correlated with renal clear-

ance.[90] A prospective intervention trial reported in 2002 showed no additional benefit of increasing peritoneal clearance over the standard dialysis prescription in terms of mortality rates.[314] Additionally the value of assessing dialysis adequacy in terms of small solute removal has been questioned from the theoretical point of view, given that the relationship between these markers and the as yet unidentified "uremic toxins" is not known. This is particularly pertinent to PD, given that it provides increased clearance of larger molecules compared with HD.

In the setting of PD, the elimination of two markers has typically been used to give an assessment of dialysis adequacy. Measurements of urea in both dialysate and blood are used to generate the parameter K_t/V. This, in combination with C_{Cr}, determined using measurements of creatinine in blood, dialysate, and urine (see Chapter 24), gives an assessment of dialytic adequacy. To obtain the weekly K_t/V_{urea} requires the measurement of volume of spent dialysate and urine for a complete 24-hour period. The concentration of urea in dialysate compared with plasma is calculated (the D/P ratio). This value is multiplied by the volume of the drained effluent to give an estimate of K_t. The calculation of "V" or volume of distribution of urea is derived from an estimate of total body water (TBW).[180,440] An estimate of weekly K_t/V_{urea} is simply the daily clearance multiplied by a factor of seven. These equations are used for both peritoneal and renal clearance and the total weekly clearance obtained by addition. Measurements of urea in plasma, urine, and dialysis fluid also enable calculation of the normalized protein catabolic rate (nPCR), a marker of protein intake that may also have prognostic significance.

The calculation of C_{Cr} is based on the clearance (C) formula:

$$C = \frac{U\,(\text{or } D) \times V}{P}$$

where U is the concentration of creatinine in urine or dialysate, V is the mean daily drain volume or urine volume (measured in liters), and P is the concentration of creatinine in the plasma. The daily clearance obtained for both urine and dialysate is added together and multiplied by seven for the total weekly C_{Cr}.

Compliance with complete collections is mandatory. To avoid sampling errors in patients who infrequently void, urine is collected over a 48-hour period. The dialysate sampling requires all effluent bags in a 24-hour period to be brought to the center renal unit. This can be difficult, since the bags are heavy and bulky. In CAPD, plasma concentrations of urea and creatinine are relatively constant, and therefore blood is drawn at any convenient time for clearance determinations. In APD, blood samples are typically collected after the overnight dialysis period. Both creatinine and urea concentration can be obtained on the same sample of urine, blood, and dialysate. It is important that glucose interference in the dialysate creatinine measurement be minimized by using an enzymatic creatinine method. The limitations of creatinine and creatinine clearance measurements have been discussed in Chapter 24, but in the setting of PD adequacy assessment it particularly should be noted that it is especially compromised at low GFR because of increased tubular secretion of creatinine and decreasing accuracy of the urine collection.

An adjunct to the assessment of adequacy in PD patients is the peritoneal equilibration test (PET).[418] The PET assesses peritoneal membrane transport characteristics in terms of solute clearances and ultrafiltration. The results are used to select a dialysis regimen appropriate to the transport characteristics of the patient (e.g., high transporters may do better on short dwell APD regimens). The PET is typically undertaken at the same time as adequacy assessments in PD patients.

The measurement of adequacy is burdensome, labor intensive, and prone to multiple measurement errors. Although dialysis center nursing staff and patients may collect the necessary samples required for adequacy testing with the utmost diligence, the very complexity and number of measurements taken will cause systematic errors. Nevertheless, in the opinion of the authors of the NKF-K/DOQI Clinical Practice Guidelines for PD Adequacy, when properly performed, these measures are reproducible enough to be useful in routine clinical practice.[294] However, an alternative, simpler, method for defining dialysis adequacy would be very useful in practice.

Complications of Dialysis

A number of diseases are associated with patients on dialysis, including cardiovascular disease, hypertension, β_2-microglobulin amyloidosis, malnutrition, and others.

Cardiovascular Disease

The risk of cardiovascular disease in patients with ESRD is far greater than in the general population. Among patients treated by HD or PD, the prevalence of coronary artery disease is approximately 40% and the prevalence of LVH is approximately 75%.[109,389] Cardiovascular mortality has been estimated to be approximately 9% per year. Even after stratification by age, gender, race, and the presence or absence of diabetes, cardiovascular mortality in dialysis patients is 10 to 20 times higher than in the general population[113,368] (Figure 45-19).

Cardiovascular disease mortality, accounting for 50% of all deaths in ESRD, is defined by death caused by arrhythmias, cardiomyopathy, cardiac arrest, myocardial infarction, atherosclerotic heart disease, and pulmonary edema. Patients with ESRD should be considered in the highest risk group for subsequent cardiovascular events. Among dialysis patients, the prevalence of congestive heart failure is approximately 40%. Both coronary artery disease and LVH are risk factors for the development of heart failure. In practice, it is difficult to determine whether cardiac failure reflects left ventricular dysfunction or extracellular fluid volume overload.

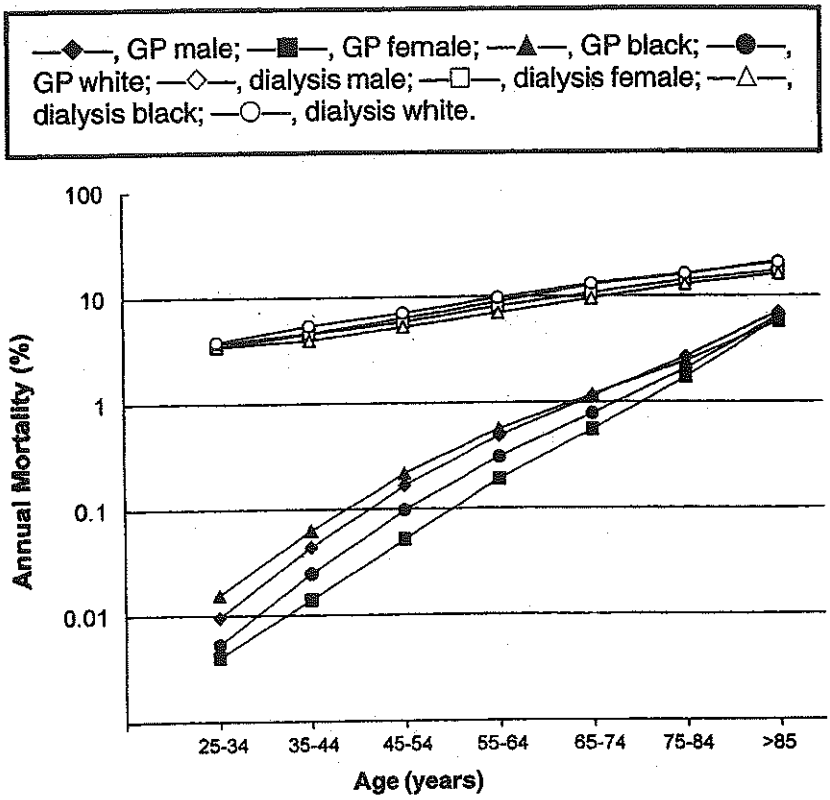

Figure 45-19 Cardiovascular disease mortality defined by death caused by arrhythmias, cardiomyopathy, cardiac arrest, myocardial infarction, atherosclerotic heart disease, and pulmonary edema in the general population (GP). Data from NCHS multiple cause of mortality data files compared with ESRD treated by dialysis. Data are stratified by age, race, and gender. *(From Foley RN, Parfrey PS, Sarnak MJ. Clinical epidemiology of cardiovascular disease in chronic renal disease. Am J Kidney Dis 1998;32 (suppl 3):S112-19, with permission from the National Kidney Foundation.)*

The risk factors for cardiovascular disease in CKD have been discussed above (and see Table 45-9). The following discussion pertains specifically to ESRD patients receiving dialysis.

Hypertension

With short hours, HD hypertension persists in many dialysis patients. Initial treatment is to ensure that excess fluid is kept to a minimum. This requires a "dry" or "target" weight to be set for the patient. The patient should reach this weight at the end of an HD session or continue at this weight during PD. The target weight is reached when there is no discernible edema and below which hypotension occurs. Blood pressure in PD patients should be below 130/80 mm Hg.[422] Standards set for HD patients are less than 140/90 mm Hg predialysis and 130/80 mm Hg postdialysis. As indicated earlier, hypertension is an early feature of CKD and its prevalence approaches 90% in patients reaching ESRD. Hypertension that is refractory to adjustments in dry weight should be treated with multiple medications, including ACE inhibitors and beta-blockers. Long-hours dialysis and salt restriction can also be considered.[65] There does, however, appear to be a U curve association of blood pressure and mortality in HD patients, with predialysis systolic blood pressure lower than 110 mm Hg also increasing risk of death.[333,467]

Dialysis Amyloid

After 10 or more years of HD, patients frequently develop carpal tunnel syndrome and evidence of amyloid deposition.[432] The main constituent of dialysis-related amyloid is β_2-microglobulin. Circulating concentrations of β_2-microglobulin can be as high as 5.0 to 10.0 mg/dL, although there is no correlation between its circulating concentration and the risk of amyloidosis. There is some suggestion that patients on CAPD are less prone to developing amyloidosis, but many still do. High-flux HD increases the removal of β_2-microglobulin and may help with symptoms. The treatment of choice is kidney transplantation.

Malnutrition

Dialysis patients with ESRD tend to have a poor appetite. Protein metabolism is also altered in the setting of chronic acidosis and low-grade inflammation. These factors in combination place patients at risk of protein and energy malnourishment. Plasma albumin is often used as a marker of malnutrition even though it is a relatively poor nutritional marker.[196,200] However, there is good evidence that the lower the plasma concentration of albumin, the worse the long-term prognosis.[110,111,310] Hypoalbuminemia is associated with increased markers of the acute phase response, such as C-reactive protein (CRP).[311,402] Persistent elevation of CRP is common in dialysis patients, and may occur in the absence of detectable infection. Episodes of peritonitis in PD patients cause significant albumin losses because of membrane leakage.

Nutritional screening is recommended in dialysis patients.[422] Such screening may involve subjective global assessment, measurement of the body mass index, a recent

history of weight loss, and the measurement of albumin. An albumin concentration of <3.5 g/dL (measured by a bromocresol green method) or <3.0 g/dL (bromocresol purple method) is indicative of undernutrition.

Vascular Calcification

It has been known for more than 100 years that patients with kidney failure have vascular calcification. In 1855, Virchow noted that vascular calcification is an "ossification, and not a mere calcification."[436] Serial x-ray studies and ultrasound imaging of large arteries confirm increased calcification in patients on dialysis over many years.[130] Studies from France have linked the presence of vascular calcification with reduced survival on dialysis.[29,30,141]

Calcification of the major arteries occurs along the intimal lining of blood vessels in association with atheroma. However, in CKD there is also medial and adventitial calcification, reducing the compliance of the vessel. This can be observed by measuring pulse wave velocities along the aorta. The pulse wave velocity is increased in stiff vessels, causing the rebound pulse wave to return more quickly to the heart during the cardiac cycle. This can cause LVH.[29] Vascular calcification has also been studied in both CKD and non-CKD populations using modern sophisticated imaging. Electron-beam computed tomography acquires serial sections of the aortic arch, the coronary vessels, and the aorta. Areas of calcification can be identified and allocated a calcium score (Agatston score).[1] This approach cannot distinguish between intimal or medial calcification but, in non-CKD patients, the higher the calcium score the more predictive of stenotic vascular disease.[208,364] Dialysis patients as young as 20 years exhibit vascular calcification,[131] and the calcium scores increased rapidly within several months when the scans were repeated. The use of calcium-containing phosphate binders may be associated with increased risk of calcification, although this remains unproven.[131] The Treat to Goal Study explored the use of a noncalcium, nonaluminum containing phosphorus binder, sevelamer hydrochloride, in 200 HD patients from Europe and North America.[69] The study demonstrated a significant attenuation in the rate of calcification of vessels with sevelamer hydrochloride at 12 months. Patients were also less likely to develop hypercalcemia and had lower plasma LDL cholesterol concentration, but there was a tendency to worsening acidosis. The hope for future studies is that attenuation of vascular calcification improves patient survival.

Studies have explored the molecular pathophysiology of vascular calcification.[385,419] Mineralization-regulating proteins are deposited at sites of vascular calcification. The generation of a matrix gamma-carboxyglutamic acid (Gla) protein knockout mouse, which exhibits extensive and lethal calcification and cartilaginous metaplasia of the media of all elastic arteries, has refocused attention on the role of Gla-containing proteins in vascular calcification.[385] A number of proteins—including matrix Gla protein, osteonectin, and osteoprotegerin—are constitutively expressed by vascular smooth muscle cells in normal media but are downregulated in calcified arteries. In calcified plaques, vascular smooth muscle cells express osteoblast-like gene expression profiles as demonstrated by in situ hybridization.[419] The identification of natural inhibitors of calcification in plasma, such as human fetuin-A (AHSG; α_2-Heremans Schmid glycoprotein) and matrix-GLA protein, suggests that the vascular endothelium may be continually subjected to calcification stresses and that regulatory systems break down in uremia. A cross-sectional study in HD patients demonstrated that AHSG concentrations were significantly lower in plasma of patients on HD than in healthy controls.[211]

Kidney Transplantation

Kidney transplantation is the most effective form of RRT, in terms of long-term survival and quality of life.[332] Since 1986, there have been over 340,000 organ transplants performed in the United States. On January 18, 2005, there were 60,534 patients on the waiting list for a kidney transplant in the United States alone.[423] A further 2418 were awaiting combined kidney and pancreas transplantation. In the United Kingdom, there has been a decline in the number of cadaveric donor transplants since 1992. Some of the shortfall has been addressed by increasing the supply of kidneys from live donation, with a threefold increase in the use of live donor transplants since 1992,[426] with no long-term detriment to the donor left with a single kidney. There is also evidence to suggest that the very best outcomes are achieved following preemptive live donor transplants.[262] An alternative method for organ procurement is the use of non–heartbeating donors. Although only slowly accepted as feasible, 2001-2002 data suggest good long-term outcomes.[280,442] On January 18, 2005 the waiting list for a kidney transplant in the United Kingdom was 6335. In 2004, 1,836 kidney transplants were performed in the United Kingdom.There has been a progressive decline in the proportion of the prevalent RRT stock made up by kidney transplant patients, from 51% in 1997 to 47% in 2001.[425] Only 28% of patients with ESRD were on the waiting list in 1998.[425]

Background

Joseph Murray in Boston performed the first successful transplant in 1954 when he performed a donor transplant from one twin to the other. In 1959 Dameshek and Schwartz used 6-mercaptopurine (6-MP) in place of irradiation to precondition patients for bone marrow transplantation. Calne developed this work with the introduction of a safer derivative of 6-MP called azathioprine (AZA). By 1963, maintenance AZA and corticosteroids became the standard regimen for kidney transplantation. Kidney transplant or "graft" survival with these treatment protocols was approximately 40% at 12 months. In the late 1970s to early 1980s cyclosporin A (Cy A) was introduced and has been the mainstay immunosuppressive regimen in combination with AZA and corticosteroids. Cy A–based protocols led to fewer episodes of acute rejection and improved graft survival at 12

months to 80% to 90%. Tacrolimus was introduced during the 1990s and more recently mycophenolate mofetil (MMF), sirolimus (Rapamycin), and everolimus (Ever) have been developed for use in kidney transplantation (see Chapter 33). Also, there has been marked progress on the development and use of biological agents (monoclonal or polyclonal antibodies directed against immune response cellular targets) to suppress the immune response to a graft in human transplant recipients. All these advancements have led to increases in graft and patient survival, with 1-year graft survival of approximately 90% being the rule rather than the exception.[105,140] By contrast, long-term graft survival remains a major problem, with half of the transplants failing within 12 years, usually as a result of chronic allograft nephropathy or death with a functioning graft. Data for the time interval 1988 to 1996 predict that the half-life will increase to almost 14 years for cadaveric grafts.[151]

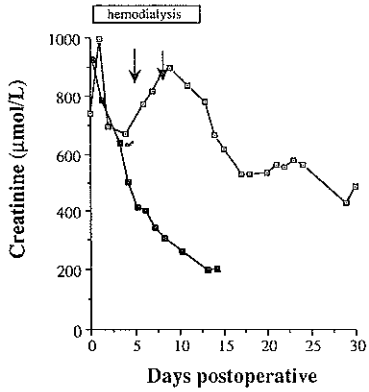

Figure 45-20 Posttransplantation biochemical profile. Open squares represent the course of a patient who experienced an early rejection episode (confirmed by biopsy, ↓) and requiring initial hemodialysis support. Solid squares represent the typical profile of an uncomplicated transplant recipient. To convert creatinine concentration in μmol/L to mg/dL, multiply by 0.011.

Preoperative Assessment

The criteria for acceptance into a transplant program differ slightly from center to center, and it is easier to consider reasons for exclusion. Candidates should not be obese (body mass index [BMI] <40 kg/m^2) and should not have (1) severe chronic lung disease, (2) inoperable ischemic heart disease, (3) active infective liver or immunological disease, (4) chronic infection (e.g., tuberculosis), (5) preexisting malignancy, or (6) lower urinary tract dysfunction. There are also two important psychological issues to be considered: the concept of organ receipt and potential difficulty in complying with immunosuppressive therapies. Age is no longer a primary issue in an otherwise healthy individual; however, only 6% of transplant recipients in the United Kingdom are over age 65.[422]

Laboratory assessment includes indicators of general operative health (e.g., electrolytes, acid-base status, clotting profile, full blood cell count, and cross-matching). In addition, full human leukocyte antigen (HLA) tissue typing is undertaken, in addition to a full screen for infectious diseases, particularly cytomegalovirus (CMV), hepatitis, herpes, and HIV status, as these infections can be activated by immunosuppressive therapy.

The donor kidney is usually placed extraperitoneally in the right or left iliac fossa. Anastomoses are constructed joining the transplant renal artery and vein to the recipient's respective iliac vessels. The ureter is joined to the bladder. The recipient native kidneys are left in situ in the majority of cases.

Postoperative Assessment

During the initial postoperative phase of 1 to 2 weeks, careful monitoring of plasma creatinine and urine output is required to monitor graft function. Most grafts produce measurable amounts of urine within a matter of hours, and this is a clear sign of a functioning graft; however, in a certain proportion, perhaps 5% to 10% of cases, there is apparently primary nonfunction. In this subgroup, continuing dialytic support is necessary. In some patients the condition resolves without treatment, but in others a percutaneous kidney biopsy may be necessary to establish whether the graft is still viable and what form of therapy should be initiated. In otherwise uncomplicated cases, the plasma creatinine concentration falls rapidly postoperatively (Figure 45-20), and consequently changes in the rate of fall of creatinine are monitored to detect early acute rejection episodes. The differential diagnosis of graft dysfunction depends on the time since the transplant. In the very early postoperative phase, this includes delayed graft function, acute vascular and cellular rejection, drug toxicity, and acute tubular damage. Relative hypotension and dehydration may also contribute. Renal artery and venous thrombosis are rare complications and ureteric obstruction can be readily diagnosed using ultrasonography. Histological examination of a transplant biopsy is necessary to aid diagnosis and adjust treatment. During acute rejection there is an interstitial cellular infiltrate, tubulitis, tubular necrosis, and a moderate or severe intimal arteritis. Unfortunately, even this approach is not completely reliable, and response or lack of it to treatment should be carefully monitored.

Immunosuppression and Therapeutic Drug Management

As mentioned earlier, the introduction of immunosuppressive drugs in the 1970s led to a vast improvement in the success rate of kidney transplantations. However, currently used drugs have potentially numerous and serious side effects. For example, treatment with prednisolone in high or prolonged doses is associated with a number of nonimmune side effects, such as development of diabetes mellitus, osteoporosis, thinning of the skin, and truncal obesity. Bone marrow suppression is the major dose-limiting side effect of treatment with azathioprine. Some side effects (infections and malignancy) reflect lack of adequate immune function and are inherent in suppressing the host immune response.

These side effects include infections such as *Pneumocystis* pneumonia and CMV, and certain malignancies such as skin cancer and lymphoma. A retrospective questionnaire study from Leeds, United Kingdom investigated 918 patients transplanted from 1967 to 1991.[250] The study demonstrated 80 different tumors in 70 patients: 42 in skin, 12 of urogenital origin, and 5 B cell lymphomas plus a number of miscellaneous tumors. In an age- and sex-matched normal population after 20 years, a 6% prevalence of cancer was observed, compared with a prevalence of 13% at 10 years and 40% at 20 years in the transplant population. Data from 2003 have shown that the prevalence of nonmelanotic skin cancer in transplant recipients at 10 years is almost 30% in the United Kingdom and 86% in Queensland, Australia.[60] These data suggest that patients receiving immunosuppressive drugs require lifelong surveillance for malignancy.

Following the introduction of Cy A in the 1980s, there was a dramatic increase in 1-year graft survival because of a reduction in the number of acute rejection episodes.[279] However, a number of important side effects have been observed. Nephrotoxicity was soon apparent in the early clinical trials[55] and remains a major clinical problem; graft biopsy may be supportive of the diagnosis if there are histological appearances of arteriolar hyalinization and glomerular ischemia leading to glomerular occlusion, and tubulointerstitial changes producing interstitial fibrosis and tubular atrophy.[138]

Clinical experience following kidney transplantation suggests that primary prophylaxis with tacrolimus results in 1-year graft and patient survival rates that are equivalent to those achieved with Cy A therapy, although with lower rates of acute rejection episodes.[129,273,328,415] Five-year follow-up data suggest improved graft survival with tacrolimus compared with Cy A.[435] Nephrotoxicity, hypertension, and post-transplant diabetes mellitus may occur and were reported commonly in the early studies.[273,328]

In 11 European centers, kidney graft recipients randomized to receive either Cy A or sirolimus as part of a triple regimen with corticosteroids and AZA had excellent graft and patient survival and incidence of acute rejection (41% and 38%).[140] Sirolimus, in contrast to Cy A, does not cause nephrotoxicity, gingival hyperplasia, or tremor. Patients treated with sirolimus have a higher incidence of thrombocytopenia, hyperlipidemia, and lymphocele formation.[203] Sirolimus and MMF have been studied in the setting of Cy A–withdrawal and Cy A–free strategies in kidney transplantation,[105,115,192,445] the hypothesis being that withdrawal or avoidance of Cy A would improve long-term outcomes, because there is no nephrotoxic stimulus. It has been shown in a multinational study to be feasible to withdraw Cy A within 3 months of transplantation.[192] Studies have also shown that sirolimus in combination with MMF is safe and associated with low rates of acute transplant rejection at 12 months.[105] These patients also received basiliximab, a monoclonal antibody to a specific target (CD 25) of T-cell activation in response to a nonidentical graft.

Cy A is insoluble and is presented for clinical use as a microemulsion. It has a narrow therapeutic window and in clinical transplantation it is important to monitor the blood level frequently. The most widely accepted practice is to monitor the "trough" blood level (C-0) just before the next dose. Accepted trough concentrations range from 100 to 200 μg/L, with higher levels for the induction phase of treatment during the first 3 months and subsequently lower maintenance levels. The trough concentration within the blood may not give a truly accurate guide to total drug exposure, since there is a wide variation in absorption over the first 2 to 4 hours following dosing.[193] This is important since most of the pharmacodynamic effects of Cy A occur within 2 hours.[145] Studies from Canada suggest that trough concentrations do not reflect clinical outcomes in terms of acute rejection rates[259] although high trough concentrations were associated with increased nephrotoxicity. A 2-hour drug (C-2) concentration correlated well with formal area under the curve (AUC) measurements and is predictive of nephrotoxicity and acute rejection episodes. In kidney transplant patients, the trough level of tacrolimus is well correlated with acute rejection episodes and nephrotoxicity.[210] Trough levels also guide sirolimus therapy.[202]

In summary, long-term graft failure is a major problem and graft loss accounts for increasing numbers of patients returning to dialysis. The most common cause, however, of graft loss is death with a functioning graft. ESRD carries a considerable burden of cardiovascular morbidity. Although some risk factors are improved following transplantation, such as volume overload and anemia, others, including dyslipidemia and hypertension, persist. The drugs used to prevent rejection can exacerbate these. The challenges to the nephrology community are complex and include increasing access to transplantation, reduction in side effects of the powerful drugs used to prevent rejection, and reduction in cardiovascular risk profiles for individual patients.

Simultaneous Pancreas-Kidney Transplantation

Patients with type 1 diabetes and stage 5 CKD with limited secondary complications of diabetes may be considered for simultaneous pancreas and kidney (SPK) transplantation. Patients tend to be younger than kidney only recipients, aged between 20 and 40 years. As of January 18, 2005, 2418 patients were awaiting combined kidney and pancreas transplantation in the United States.[423] More than 90% of pancreas transplants registered until 1996 were performed in the United States, but expertise is growing in other countries. Graft and patient survival rates have been calculated for more than 3500 recipients of an SPK transplant in the United States from 1994 to 1997 based on data reported to the United Network for Organ Sharing (UNOS) renal registry database.[52] The 1-year graft survival was 90% and patient survival around 93%. At 5 years, the graft survival was in excess of 70% and patient survival 85%. These results compare favorably with cadaveric kidney–only transplantation in diabetes. The main reason for the survival advantage

of SPK over kidney-only is the fact that younger donors and recipients are selected. A separate prospective observational study has examined the impact of SPK transplant in terms of quality of life.[139] At 3 years, SPK patients report greater improvements than kidney-only recipients in physical functioning, bodily pain, general health, and perception of greater benefits to secondary complications.

The surgical technique for SPK involves whole organ pancreas transplant with the duodenal segment draining into the urinary bladder through a duodenocystostomy. The kidney is attached as usual to the iliac vessels and the donor ureter is inserted into the bladder separately. Alternatively the pancreas can be drained enterically. This distinction is important since there are metabolic consequences outlined below. Postoperatively blood glucose concentrations are monitored closely and intravenous insulin is given as necessary. Exocrine pancreatic secretion can be measured in the urine. The major fear is rejection and a number of parameters are monitored including plasma glucose, amylase, lipase, and 12- or 24-hour urinary amylase. Because of high fluid, bicarbonate, and electrolyte losses into the urine, there is an increased need for supplementation in SPK recipients although this is usually self-limiting. Hyperamylasemia is common postoperatively and may or may not signify allograft rejection. Immunosuppressive schedules will vary between centers and include induction therapy with monoclonal or polyclonal anti–T-cell agents and a combination of the drugs outlined above. Diagnosis of pancreatic rejection in the absence of a simultaneous kidney transplant is very difficult. Signs of rejection include fever, pain, hematuria, reduction of urinary amylase, and unexplained hyperglycemia. Organ scanning and biopsy are also used. However, the function of the kidney in SPK mirrors the pancreas and therefore immunosuppression can be tailored to the requirements of the kidney.

For patients with bladder drainage, enteric conversion may be required for refractory problems, such as dehydration, metabolic acidosis, chronic urethritis caused by trypsinogen activation, urinary tract infections, and recurrent reflux pancreatitis. This involves an anastomosis between the graft duodenal segment and the recipient small bowel.

CHAPTER 46

Physiology and Disorders of Water, Electrolyte, and Acid-Base Metabolism*

James Stacey Klutts, M.D., Ph.D.,
and Mitchell G. Scott, Ph.D.

Mammalian adaptation to terrestrial life has involved the development of complex physiological systems to maintain the composition of their internal milieu. These include a variety of chemical buffers and highly specialized mechanisms of the lungs and kidneys that work together to regulate water, electrolytes, and pH between the intracellular and extracellular compartments. Perturbations in the dynamic equilibria that exist for water, electrolytes, and pH may arise from external (e.g., trauma, changes in altitude, ingestion of toxic substances) or internal (e.g., normal metabolism and disease states) sources. Correction of these imbalances by buffers and the pulmonary and renal compensatory mechanisms may not always be adequate, at which time the clinical laboratory can provide valuable information for guiding therapy.

TOTAL BODY WATER—VOLUME AND DISTRIBUTION

At birth, ~75% of total body mass is water, and from roughly 1 year of age through middle age, this value is ~60% for the average male and ~55% for females. After middle age this falls to ~50%. As depicted in Figure 46-1, approximately two thirds of total body water (TBW) is distributed into the intracellular fluid (ICF) compartment, and one third exists in the extracellular fluid (ECF) compartment. The ICF and ECF compartments are physically separated by the cellular plasma membrane. The ECF may be further subdivided into the interstitial (approximately three fourths of ECF) and intravascular (approximately one fourth of ECF) fluid compartments, which are separated by the capillary endothelium. The larger blood vessels contain additional layers of smooth muscle and connective tissue but constitute a relatively small surface area for exchange compared with the capillary beds. Within the intravascular (whole blood) compartment, *plasma,* the liquid fraction, constitutes ~3.5 L for the average adult having a hematocrit of ~40% and a 5 L blood volume. Although other clinically relevant ECF compartments (e.g., cerebrospinal fluid [CSF] and urine) may be analyzed in the clinical laboratory, the majority of laboratory tests used to determine hydration status, electrolytes, and acid-base status are performed on samples from the *intravascular* (plasma, serum, or whole blood) compartment.

The minimum daily requirement for water can be estimated from renal (~1200 mL in urine) and "insensible" losses (~200 mL due to evaporation from the skin and respiratory tract). Activity, environmental conditions, and disease all have dramatic effects on daily water (and electrolyte) requirements. However, on average, an adult must take in 1.0 to 1.5 L of water daily to maintain fluid balance. Because primary regulatory mechanisms are designed to first maintain *intracellular* hydration status, uncorrected imbalances in TBW are initially reflected in the ECF compartment. Table 46-1 lists common causes and clinical

*The authors acknowledge the original contributions by Norbert W. Tietz, Elizabeth L. Pruden, Ole Siggaard-Andersen, and Jonathan W. Heusel, on which portions of this chapter are based.

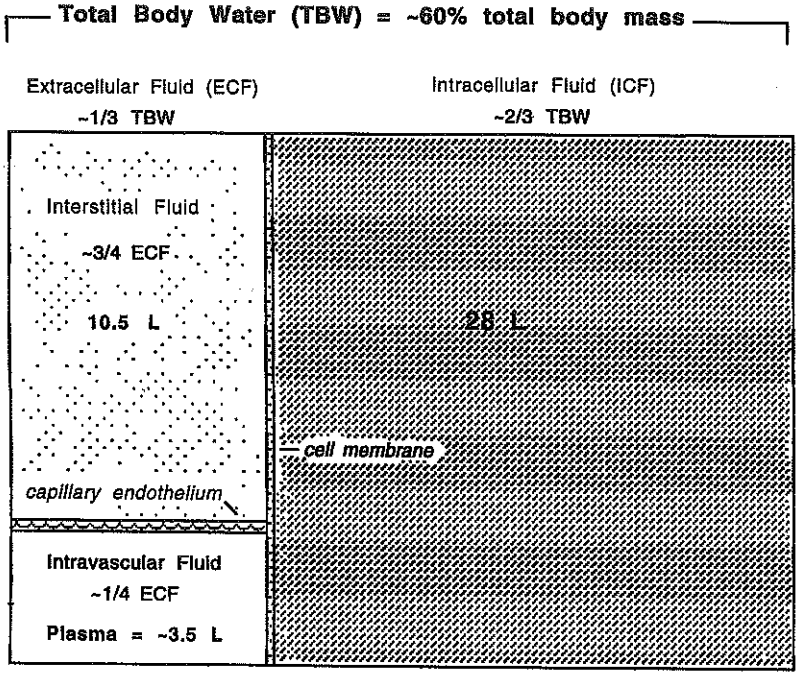

Figure 46-1 Volume and distribution of total body water. Note that the intracellular and ECF compartments (ICF and ECF, respectively) are separated by cellular plasma membranes, and within the ECF, interstitial and intravascular fluids are separated by the capillary endothelium. The volumes indicated represent water and not total volume.

TABLE 46-1 Causes and Clinical Manifestations of Changes in Extracellular Fluid (ECF) Volume

	Clinical Manifestations	Causes
ECF loss	Thirst, anorexia, nausea, lightheadedness, orthostatic hypotension, syncope, tachycardia, oliguria, decreased skin turgor and "sunken eyes," shock, coma, death	Trauma (and other causes of acute blood loss), "third-spacing" of fluid (e.g., burns, pancreatitis, peritonitis), vomiting, diarrhea, diuretics, renal or adrenal (i.e., sodium wasting) disease
ECF gain	Weight gain, edema, dyspnea (due to pulmonary edema), tachycardia, jugular venous distention, portal hypertension, esophageal varices	Heart failure, hepatic cirrhosis, nephrotic syndrome, iatrogenic (intravenous fluid overload)

manifestations of expansion and contraction of the ECF compartment.

The intravascular fluid compartment (including blood cells) represents the effective circulating or blood volume, which is the portion of the ECF perfusing the body tissues. The human body has exquisitely sensitive receptors called "baroreceptors" designed to sense both the osmotic pressure and the blood volume in the right atrium, aortic arch, and kidney. During certain pathological conditions (e.g., congestive heart failure, hepatic cirrhosis, nephrotic syndrome), the baroreceptors detect a decrease in the blood volume despite an overall expansion of the ECF. The excess fluid in the ECF compartment collects in the tissues (causing edema) and thus is not sensed by the baroreceptors. Compensatory mechanisms involve the renal retention of sodium to expand the intravascular volume, leading to a vicious cycle of fluid retention in the face of an expanding ECF compartment.

WATER AND ELECTROLYTES—COMPOSITION OF BODY FLUIDS

The major ions of body fluids are collectively called electrolytes and constitute the majority of osmotically active particles. The primary cationic (positively charged) electrolytes are sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), and magnesium (Mg^{2+}), whereas the anionic (negatively charged) electrolytes include chloride (Cl^-), bicarbonate (HCO_3^-), phosphate (HPO_4^{2-}, $H_2PO_4^-$), sulfate (SO_4^{2-}), organic ions such as lactate, and negatively charged proteins. The electrolyte concentrations of the body fluid compartments are shown in Table 46-2. Na^+, K^+, Cl^-, and HCO_3^- in the plasma or serum are commonly analyzed in an *electrolyte profile,* because their concentrations provide the most relevant information about the osmotic, hydration, and pH status of the body. Although hydrogen ion (H^+) chemically is a cation, its concentration is approximately 1 million–fold

TABLE 46-2 Electrolyte and Water Composition of Body Fluid Compartments*

Component	Plasma	Interstitial Fluid	Intracellular Fluid†
Volume, H_2O	3.5 L	10.5 L	28 L (TBW = 42 L)
Na^+	142	145	12
K^+	4	4	156
Ca^{2+}	6	2-3	3
Mg^{2+}	2	1-2	26
Trace elements	1		
Total cations	155		
Cl^-	103	114	4
HCO_3^-	27	31	12
$Protein^-$	16	—	55
$Organic\ acids^-$	5	—	—
HPO_4^{2-}	2		
SO_4^{2-}	1		
Total anions	154		

TBW, Total body water.
*All electrolyte values are expressed in mEq/L of *fluid*. Because the H_2O content of plasma is ~90% by volume, the corresponding electrolyte concentrations in plasma water are ~10% higher. Note that the *molar concentration* of divalent ions is one-half the depicted value.
†These values are derived from skeletal muscle.

lower in plasma than the major electrolytes listed in Table 46-2 (10^{-9} mol/L vs. 10^{-3} mol/L) and thus is negligible in terms of osmotic activity. The total number of positive ions (including H^+) *must* equal that of the negative ions for electrical neutrality.

Any increase in the concentration of one anion is accompanied either by a corresponding decrease in other anions or by an increase in one or more cations or both, so total electrical neutrality is invariably maintained. Similarly, any decrease in the concentration of anions involves either a corresponding increase in other anions, or a decrease in cations, or both. In the case of polyvalent ions (e.g., Ca^{2+} or Mg^{2+}), it is important to distinguish between the substance concentration of the ion itself and the concentration of the ion charge. Thus although the concentration of total calcium ions in normal plasma is 2.5 mmol/L, the concentration of the total calcium ion *charge* is 5.0 mmol/L (also called 5 milliequivalents per liter [mEq/L]). This law of *electrical neutrality* should not be confused with acid-base neutrality (pH = 7.0, where the activity of H^+ equals the activity of OH^-).

The special nature of H^+ is discussed below in the section about acid-base physiology. The special functions of calcium, magnesium, phosphates, amino acids, iron, and the trace elements are considered separately in Chapters 20 and 30.

Extracellular and Intracellular Compartments

The extracellular compartment is composed of plasma and interstitial fluid.

Plasma

Plasma, which is of main interest in discussion of water and electrolytes, generally has a volume of 1300 to 1800 mL/m^2 of body surface and constitutes approximately 5% of the body volume (~3.5 L for a 66-kg subject). Generally, total body volume is derived from body mass by using an estimated body density of 1.06 kg/L. The electrolyte composition of venous plasma is summarized in Table 46-2. The mass concentration of water in normal plasma is about 0.933 kg/L, depending on the protein and lipid content (see Electrolyte Exclusion Effect in Chapter 27). Thus a concentration of sodium in the plasma of 140 mmol/L would correspond to a molality of sodium in plasma water of 150 mmol/kg H_2O (140 mmol/L divided by 0.933 kg/L). The total weight (mass) of 1 L of plasma is about 1.026 kg; thus the total weight of solute in 1 L of plasma is about 1.026 – 0.933 = 0.093 kg. The concentration of net protein ions in plasma is ~12 mmol/L, with the charge mainly due to albumin, as the charge of globulins is negligible.[9]

Interstitial Fluid

Interstitial fluid is essentially an ultrafiltrate of blood plasma (see Figure 46-1). When all extracellular spaces except plasma are included, the volume accounts for about 26% (~17 L) of the total body volume. Plasma is separated from the interstitial fluid by the endothelial lining of the capillaries, which acts as a semipermeable membrane and allows passage of water and diffusible solutes but not compounds of large molecular mass, such as proteins. However, this "impermeability" is not absolute, as demonstrated by the varying (although low) concentration of protein in intersti-

tial fluids. In pathological conditions causing "shock," such as bacterial sepsis, the permeability of the vascular endothelium increases dramatically, resulting in leakage of albumin, a reduction in the effective circulating volume, and hypotension. If not aggressively treated with antibiotics, intravenous fluids, and/or vasopressors, this condition can result in death secondary to decreased cerebral perfusion.

Intracellular Fluid

The exact composition of ICF is extremely hard to measure because of the relative unavailability of cells free of contamination. Although erythrocytes are easily accessible, it would be incorrect to make any generalizations based on the composition of these highly specialized cells. Data on cell composition (see Table 46-2), therefore, are considered only approximations. The volume of the ICF constitutes ~66% of the total body volume (see Figure 46-1).

Reasons for Composition Differences of Body Fluids

The composition of ICF can differ markedly from that of the ECF because of the separation of these compartments by the cell membrane. The composition differences are a consequence of both the Gibbs-Donnan equilibrium and active and passive transport of ions.

Gibbs-Donnan Equilibrium

Two solutions separated by a semipermeable membrane will establish an equilibrium so that all ions are equally distributed in both compartments provided that the solutes can move freely through the membrane. At the state of equilibrium, the total ion concentration and therefore the total concentration of osmotically active particles (osmolalities) are equal on both sides of the membrane.

If solutions on two sides of a membrane contain different concentrations of ions that cannot freely move through the membrane (e.g., proteins), distribution of the diffusible ions (e.g., electrolytes) at the steady state will be unequal, but the product of the concentrations of ions in one compartment is equal to the product of ions in the other compartment (Gibbs-Donnan law). Also the law of electrical neutrality is obeyed for both compartments. An example of the uneven distribution of an ion in two compartments with different protein content (nondiffusible ions) is the concentration of chloride ions in plasma and CSF. As a result of the increased selectivity of the blood-brain barrier against proteins, Cl^- ions are ~15% higher in CSF to establish electrical and osmotic equilibrium.[31] Calculations that demonstrate these principles can be found in the first edition of this textbook (pp. 1225-1227).[29]

Cells that contain nondiffusible protein anions can withstand only a limited and temporary difference in osmotic pressure across the cell membrane. The osmotic pressure is normally identical inside and outside the cells because the cell membrane can correct concentration differences by excluding some small ions by active, energy requiring, transport processes. If these processes cease, the cells gradually swell and eventually burst (osmotic lysis).

Distribution of Ions by Active and Passive Transport

Examination of Table 46-2 reveals that the electrolyte compositions of blood plasma and interstitial fluid (both ECFs) are similar, but their compositions differ markedly from that of ICF. The major extracellular ions are Na^+, Cl^-, and HCO_3^-, although in ICF the main ions are K^+, Mg^{2+}, organic phosphates, and protein. This unequal distribution of ions is due to an active transport of Na^+ from inside to outside the cell against an electrochemical gradient. This process requires energy supplied by the metabolic processes in the cell (e.g., glycolysis). An active sodium pump deriving its energy from adenosine triphosphate (ATP) is present in most cell membranes, frequently coupled with a transport of K^+ into the cell. The Na^+/K^+ pump is a heterodimer consisting of a catalytic transmembrane α-subunit that is about 1000 amino acid residues long, and an associated, smaller β-subunit.[13] The internal surface has a catalytic binding site for ATP and a binding site for Na^+. The external surface has a binding site for K^+. ATP phosphorylates an aspartic acid residue of the ATPase, resulting in a conformation change of the protein that ultimately triggers the expulsion of three sodium ions with a concomitant uptake of two potassium ions.[13]

In addition to the Na^+/K^+-ATPase, there is also a ubiquitous Na^+-H^+ exchanger (often referred to as an antiporter) that actively pumps H^+ out of the ICF in exchange for Na^+.[18] This exchanger is critical for maintaining intracellular pH homeostasis and volume in many cell types. At least six different isoforms of this transmembrane protein have been identified, and the regulation and tissue distribution of these differ.[18] Of particular importance is the role of this exchanger for acid-base regulation in renal tubular cells as discussed later in this chapter.

ELECTROLYTES

Homeostasis and disorders of Na^+, K^+, Cl^-, and HCO_3^- are separately considered.

Sodium

Disorders of Na^+ homeostasis can occur because of excessive loss, gain, or retention of Na^+ or because of excessive loss, gain, or retention of H_2O. It is difficult to separate disorders of Na^+ and H_2O balance because of their close relationship in establishing normal osmolality in all body water compartments. As described in detail in Chapter 45, the primary organ for regulating body water and extracellular Na^+ is the kidney. However, as a brief introduction to this section, it is important to remind the reader of the functions of healthy kidneys. In the proximal tubules, 60% to 70% of the filtered Na^+ is actively reabsorbed, with H_2O and Cl^- following passively to maintain electrical neutrality and osmotic equivalence. In the descending loop of Henle, H_2O, but not

electrolytes, is passively reabsorbed because of the high osmotic strength of the interstitial fluid in the specialized environment of the renal medulla. In the ascending loop of Henle, Cl^- is reabsorbed actively, with Na^+ following. At the level of the distal tubule, the first of the two primary Na^+/H_2O regulating processes occurs. Here, aldosterone stimulates the distal tubules to reabsorb Na^+ (with water following passively) and secrete K^+ (and to a lesser extent, H^+) to maintain electrical neutrality. Aldosterone is produced by the adrenal cortex in response to the angiotensin II derived via the action of renin (see Chapter 45). The secretion of renin by renal juxtaglomerular cells is stimulated by low chloride, β-adrenergic activity, and low arteriolar pressure.[26] Thus when the kidneys are hypoperfused (as occurs when blood volume decreases or if the renal arteries are obstructed), the distal tubules, under the influence of aldosterone, reclaim Na^+. Further water regulation in the kidney occurs from the distal tubule through the collecting duct where tubular permeability to H_2O is under the influence of antidiuretic hormone (ADH) (see Chapters 45 and 50). ADH (also called vasopressin) is released by the posterior pituitary under the influence of baroreceptors in the aortic arch and hypothalamic chemoreceptors that are responsive to circulating osmolality, which is primarily a reflection of Na^+ concentration.[27] When blood volume is decreased or when plasma osmolality is increased, ADH is secreted, tubular permeability to H_2O increases, and H_2O is reabsorbed in an attempt to restore blood volume or to decrease osmolality. In contrast, when blood volume is increased or osmolality decreased, ADH secretion is inhibited, and more H_2O is excreted in the urine (diuresis).

The body's only other mechanism for restoring Na^+/H_2O homeostasis is ingestion of H_2O. Thirst is stimulated by either decreased blood volume or a hyperosmotic condition. It is important to remember that the receptors that influence renal handling of Na^+ and H_2O, and thirst, sense changes only in the intravascular blood volume and not the total ECF. Furthermore, laboratory assessment of water and electrolyte disorders is primarily made from the blood volume (plasma). As discussed in subsequent sections, the clinician must assess the status of TBW and blood volume before interpretation of laboratory values in the diagnosis of water electrolyte disorders. The physical findings and clinical manifestations of these disorders are every bit as important as laboratory values (see Table 46-1).

Hyponatremia

Hyponatremia is defined as a decreased plasma Na^+ concentration (<136 mmol/L). Hyponatremia typically manifests itself clinically as nausea, generalized weakness, and mental confusion at values <120 mmol/L, ocular palsy at <110 mmol/L, and severe mental impairment between 90 and 105 mmol/L.[25,28] The central nervous system (CNS) symptoms are primarily due to movement of H_2O into cells to maintain osmotic balance and thus swelling of CNS cells. The rapidity of the development of hyponatremia influences the concentrations of Na^+ at which symptoms develop; i.e., clinically apparent symptoms may manifest at slightly higher Na^+ concentrations (~125 mmol/L) when hyponatremia develops rapidly.[25]

Hyponatremia has occurred in the settings of hypoosmotic, hyperosmotic, and isosmotic plasma; thus the measurement (or occasionally a calculation) of plasma osmolality is an important initial step in the assessment of hyponatremia. Of these, the most common is hypoosmotic hyponatremia, since Na^+ is the primary determinant of plasma osmolality. Figure 46-2 describes an algorithm for laboratory measurements and physical examination findings in the differential diagnosis of a plasma Na^+ <135 mmol/L.

Hypoosmotic Hyponatremia

Typically when the plasma Na^+ concentration is low, the calculated or measured osmolality will also be low. This type of hyponatremia can be due to either excess loss of Na^+ (*depletional hyponatremia*) or increased ECF volume (*dilutional hyponatremia*). Differentiating these initially requires a clinical assessment of TBW and ECF volume by a history and physical examination.

Depletional hyponatremia (excess loss of Na^+) is almost always accompanied by a loss of ECF water, but to a lesser extent than the Na^+ loss. Hypovolemia is apparent in the physical examination (orthostatic hypotension, tachycardia, decreased skin turgor). Loss of isosmotic or hypertonic fluid is the cause and this can occur through renal or extrarenal losses. If urine Na^+ is low (generally <10 mmol/L), the loss is extrarenal (see Figure 46-2) because the kidneys are properly retaining filtered Na^+ in response to increased aldosterone (stimulated by the hypovolemia and hyponatremia). Causes of extrarenal loss of Na^+ in excess of H_2O include losses from the gastrointestinal tract or skin (see Figure 46-2).

Alternatively, if urine Na^+ is elevated in this setting (generally >20 mmol/L), renal loss of Na^+ is likely. Renal loss of Na^+ occurs with (1) osmotic diuresis, (2) thiazide diuretics (that inhibit reabsorption of Cl^- and Na^+ in the ascending loop), (3) adrenal insufficiency (the absence of aldosterone and cortisone prevents distal tubule reabsorption of Na^+), or (4) "potassium-sparing" diuretics such as spironolactone that block aldosterone-mediated reabsorption of Na^+ in the distal tubules. Renal loss of Na^+ in excess of H_2O can also occur in metabolic alkalosis because of prolonged vomiting, because increased renal HCO_3^- excretion is accompanied by Na^+ ions. In this case, urine sodium is elevated (>20 mmol/L), but urine chloride remains low. In proximal renal tubular acidosis (RTA), bicarbonate is lost because of a defect in HCO_3^- reabsorption and Na^+ is again co-excreted to maintain electrical neutrality.

Dilutional hyponatremia is a result of excess H_2O retention and can often be detected during the physical examination as the presence of weight gain or edema. In advanced renal failure, water is retained because of decreased filtration and H_2O excretion. However, the remaining functional

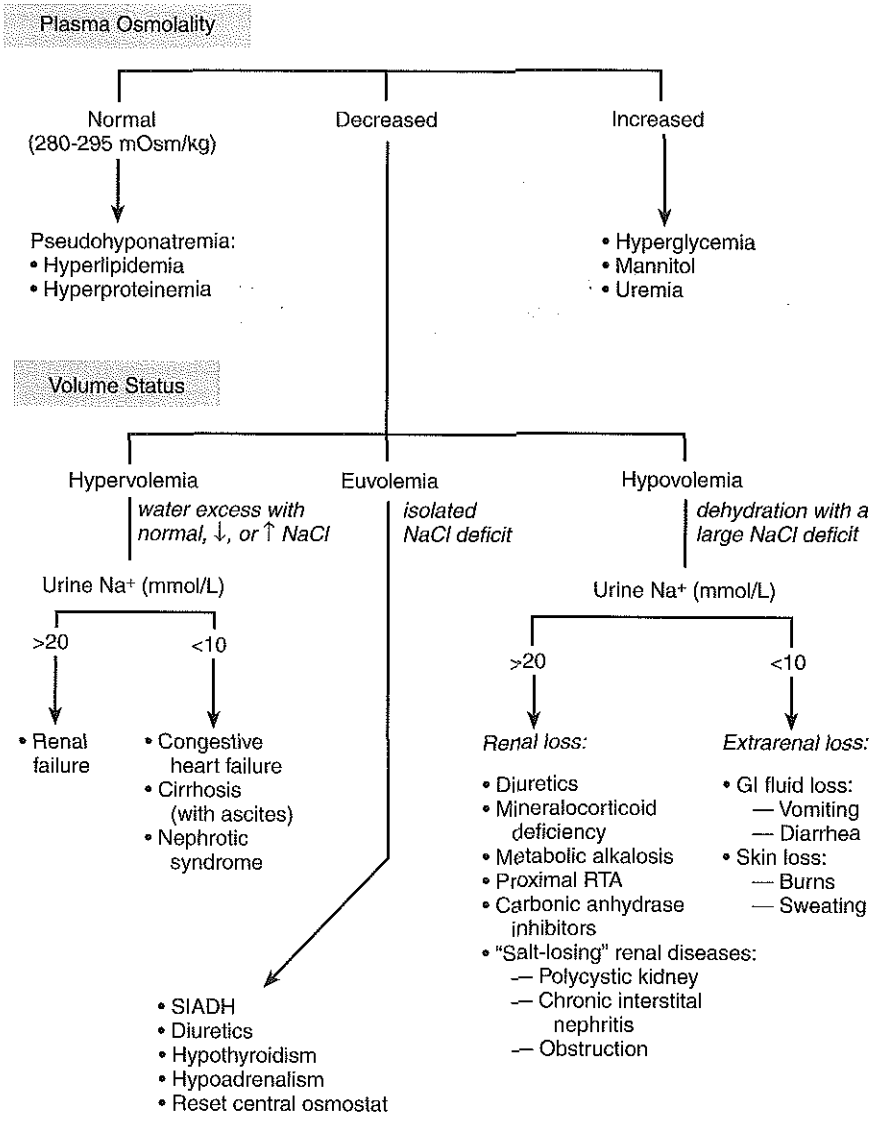

Figure 46-2 Algorithm for the differential diagnosis of hyponatremia. *(Modified from Kirkpatrick W, Kreisberg R. Acid-base and electrolyte disorders. In: Liu P, ed. Blue book of diagnostic tests. Philadelphia: WB Saunders Co, 1986:239-54.)*

nephrons will excrete excess Na^+ secondary to the increased aldosterone that is secreted in response to reduced glomerular pressure in the diseased nephrons.

When ECF is increased but the blood volume is decreased, in congestive heart failure (CHF), hepatic cirrhosis, or the nephrotic syndrome, a vicious cycle is established. The decreased blood volume is sensed by baroreceptors and results in increased aldosterone and ADH, even though ECF volume is excessive. The kidneys reabsorb Na^+ and H_2O in response to the increased aldosterone and ADH in an attempt to restore the blood volume, but this simply results in further increases in the ECF and further dilution of Na^+. It is important to note that the physical findings of congestive heart failure can be subtle, often making diagnosis difficult. Brain natriuretic peptide (BNP), a myocardial cell-derived protein, is elevated in many undiagnosed cases of heart failure.[24] As such, this hormone has become a useful marker for the diagnosis and monitoring of this disorder in patients (see Chapter 44). The release of BNP occurs in response to ventricular stretch, and the natriuretic action of the hormone suggests that one of its functions is to reduce ECF volume and thus cardiac afterload.[24] Furthermore, therapy with BNP analogs has shown promise in the treatment of CHF.[14]

In hypoosmotic hyponatremia with a normal volume status, the most common etiologies are the syndrome of inappropriate ADH (SIADH), primary polydipsia, hypothyroidism, and adrenal insufficiency (see Figure 46-2). SIADH is usually a result of ectopic or otherwise "inappropriate" ADH production arising from a variety of conditions[11] (see Chapters 45 and 50) and results in excessive H_2O retention. SIADH is often diagnosed when a urine osmolality that is greater than plasma osmolality (usually by more than >100 mOsmol/kg) is observed in the setting of hyponatremia, *but only when renal, adrenal, and thyroid functions are normal.* Hypothyroidism impairs free H_2O excretion, whereas in adrenal insufficiency, Na^+ is lost in preference to K^+ reabsorption. Finally, euvolemic hyponatremia can be

found in polydipsia when water intake is greater than the renal capacity to excrete the excess H_2O. This is most often the result of psychiatric illness, but diseases that cause hypothalamic disorders, such as sarcoidosis, may also cause polydipsia by altering the thirst reflex (see Figure 46-2).

Hyperosmotic Hyponatremia

Hyponatremia occurs with an increased amount of other solutes in the ECF, causing an extracellular shift of water or intracellular shift of Na^+ to maintain osmotic balance between the ECF and ICF compartments. The most common cause of this type of hyponatremia is severe hyperglycemia. As a general rule, the Na^+ decreases ~1.6 mmol/L for every 100 mg/dL increase of glucose above 100 mg/dL. The clinical use of mannitol for osmotic diuresis can have a similar effect.

Isosmotic Hyponatremia

If the measured Na^+ concentration in plasma is decreased, but measured plasma osmolality, glucose, and urea are normal, the only explanation is pseudohyponatremia caused by the *electrolyte exclusion effect* (see Chapter 27). This occurs when Na^+ is measured by either flame emission spectrophotometry or by an indirect ion-selective electrode in patients with severe hyperlipidemia or in states of hyperproteinemia (e.g., paraproteinemia of multiple myeloma).

Hypernatremia

Hypernatremia (plasma Na^+ >150 mmol/L) is always hyperosmolar. Symptoms of hypernatremia are primarily neurological (because of intraneuronal loss of H_2O to the ECF) and include tremors, irritability, ataxia, confusion, and coma.[25] As with hyponatremia, the rapidity of the development of hypernatremia will determine the plasma Na^+ value at which symptoms occur. Acute development may cause symptoms when Na^+ reaches 160 mmol/L, although in chronic hypernatremia, overt symptoms may not occur until Na^+ exceeds 175 mmol/L. In chronic hypernatremia, the intracellular osmolality of CNS cells will increase to protect against intracellular dehydration. Because of this, rapid correction of hypernatremia can cause dangerous cerebral edema, as CNS cells will take up too much water if the ICF is hyperosmotic when normonatremia is achieved.[25]

In many cases, the symptoms of hypernatremia may be masked by underlying conditions that contributed to the development of the hypernatremia. Indeed, most cases of hypernatremia occur in patients with altered mental status or in infants, both of whom may have difficulty in rehydrating themselves despite a normal thirst reflex. Thus hypernatremia will rarely occur in an alert patient with a normal thirst response who has access to water.

In general, hypernatremia arises in the setting of (1) hypovolemia (either excessive water loss or failure to replace normal water losses), (2) hypervolemia (a net Na^+ gain in excess of water gain), or (3) normovolemia. Again, assessment of TBW status by physical examination and measurement of urine Na^+ and osmolality are important steps in establishing a diagnosis for hypernatremia (Figure 46-3).

Hypovolemic Hypernatremia

Hypernatremia in the setting of decreased ECF is caused by the renal or extrarenal loss of hypoosmotic fluid leading to dehydration. Thus once hypovolemia is established, measurement of urine Na^+ and osmolality is used to determine the source of fluid loss. Patients who have large extrarenal losses have a concentrated urine (>800 mOsmol/L) with low urine Na^+ (<20 mmol/L), reflecting the proper renal response to conserve Na^+ and water as a means to restore ECF volume. Extrarenal causes include diarrhea, skin (burns or excessive sweating), or respiratory losses coupled with failure to replace the lost water. When gastrointestinal loss is excluded, and the patient has normal mental status and access to H_2O, a hypothalamic disorder (tumor or granuloma) should be suspected, because the normal thirst response should always replace insensible water losses.[25]

Renal causes of water loss in excess of Na^+ can occur with osmotic diuresis or with thiazide diuretics coupled with decreased water intake. In the latter setting, the decreased ECF will lead to increased Na^+ reabsorption in the distal tubules, a site distal to that of the thiazide-induced inhibition of Na^+ and H_2O reabsorption. Although this increased Na^+ reabsorption will lead to hypernatremia, there will still be excess Na^+ in the urine, causing further diuresis. In the former setting, chemoreceptors sensing peripheral hypernatremia will prevent Na^+ reabsorption at the distal tubule, leading to massive diuresis and elevated urine Na^+. Therefore, in either of these settings, urine volume will be high, urine osmolality normal to low, and urine Na^+ high.

Normovolemic Hypernatremia

Hypernatremia in the presence of normal ECF volume is often a prelude to hypovolemic hypernatremia. Insensible losses through the lung or skin again must be suspected and are characterized by concentrated urine as the kidneys function to conserve water. Another cause of normovolemic hypernatremia is water diuresis, which is manifested by polyuria (see Figure 46-3). The differential for polyuria (generally defined as >3 L urine output/day) is either a water or a solute diuresis. Solute diuresis is exemplified by the osmotic diuresis of diabetes mellitus and generally is characterized by urine osmolality >300 mOsmol/L and hyponatremia (see previous discussion in this chapter). A water (or solvent) diuresis is a manifestation of diabetes insipidus (DI) and is characterized by dilute urine (osmolality <250 mOsmol/L) and slight hypernatremia.[25] DI can be either central or nephrogenic.[20] Central DI is due to decreased or total lack of ADH secretion as a result of head trauma, hypophysectomy, pituitary tumor, or granulomatous disease. Nephrogenic DI is due to renal resistance to ADH as a result of drugs (e.g., lithium, demeclocycline, amphotericin, and propoxyphene); diseases such as sickle cell anemia and Sjögren's syndrome, which affect collecting

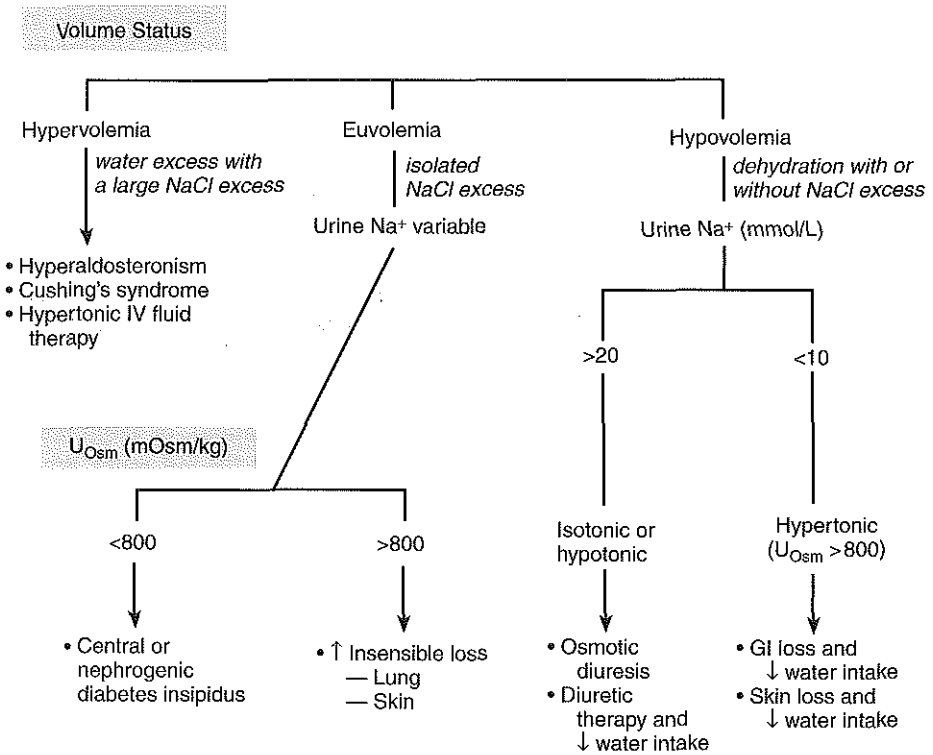

Figure 46-3 Algorithm for the differential diagnosis of hypernatremia. *(Modified from Kirkpatrick W, Kreisberg R. Acid-base and electrolyte disorders. In: Liu P, ed. Blue book of diagnostic tests. Philadelphia: WB Saunders Co, 1986:239-54.)*

duct responsiveness to ADH; or, more rarely, mutant ADH receptors.[2] Central DI is usually treated with vasopressin, whereas nephrogenic DI is treated by discontinuing the responsible drug or providing easy and frequent access to drinking water.

Hypervolemic Hypernatremia

The presence of excess TBW and hypernatremia indicates a net gain of water and Na^+, with Na^+ gain in excess of water (see Figure 46-3). This condition is commonly observed in hospital patients receiving hypertonic saline or sodium bicarbonate. Other causes of hypervolemic hypernatremia include hyperaldosteronism and Cushing's syndrome (see Chapters 24 and 51). Excess aldosterone and cortisol (which also act as ligands for the distal tubule aldosterone receptor) results in excess Na^+ and water retention. Corticosteroid therapy can have similar effects as well.

Potassium

The total body potassium of a 70 kg subject is ~3.5 mol (40 to 59 mmol/kg) of which only 1.5% to 2% is present in the ECF. Nevertheless, plasma K^+ is a relatively good indicator of total K^+ stores with only a few exceptions. Because extracellular K^+ concentrations are maintained at the expense of the intracellular supply, plasma K^+ concentration can initially be normal and belie a total body deficit of up to 200 mmol.

Disturbance of K^+ homeostasis has serious consequences. For example, decrease of extracellular K^+ (hypokalemia) is characterized by muscle weakness, irritability, and paralysis. Plasma K^+ concentrations less than 3.0 mmol/L are associated with marked neuromuscular symptoms and indicate a critical degree of intracellular depletion. At lower concentrations, tachycardia and specific cardiac conduction effects are apparent by electrocardiographic examination (flattened T waves) and can lead to cardiac arrest.[25]

Abnormally high extracellular K^+ (hyperkalemia) concentrations produce symptoms of mental confusion, weakness, tingling, flaccid paralysis of the extremities, and weakness of the respiratory muscles.[25] Cardiac effects of hyperkalemia include bradycardia and conduction defects evident on the electrocardiogram by prolonged PR and QRS intervals and "peaked" T waves. Prolonged severe hyperkalemia >7.0 mmol/L can lead to peripheral vascular collapse and cardiac arrest. There is individual variability in the concentrations of K^+ at which symptoms become apparent, but symptoms are almost always present at K^+ concentrations >6.5 mmol/L. Concentrations >10.0 mmol/L are in most cases fatal.

Hypokalemia

Causes of *hypokalemia* (plasma K^+ <3.5 mmol/L) are classified as redistribution of extracellular K^+ into ICF, or true K^+

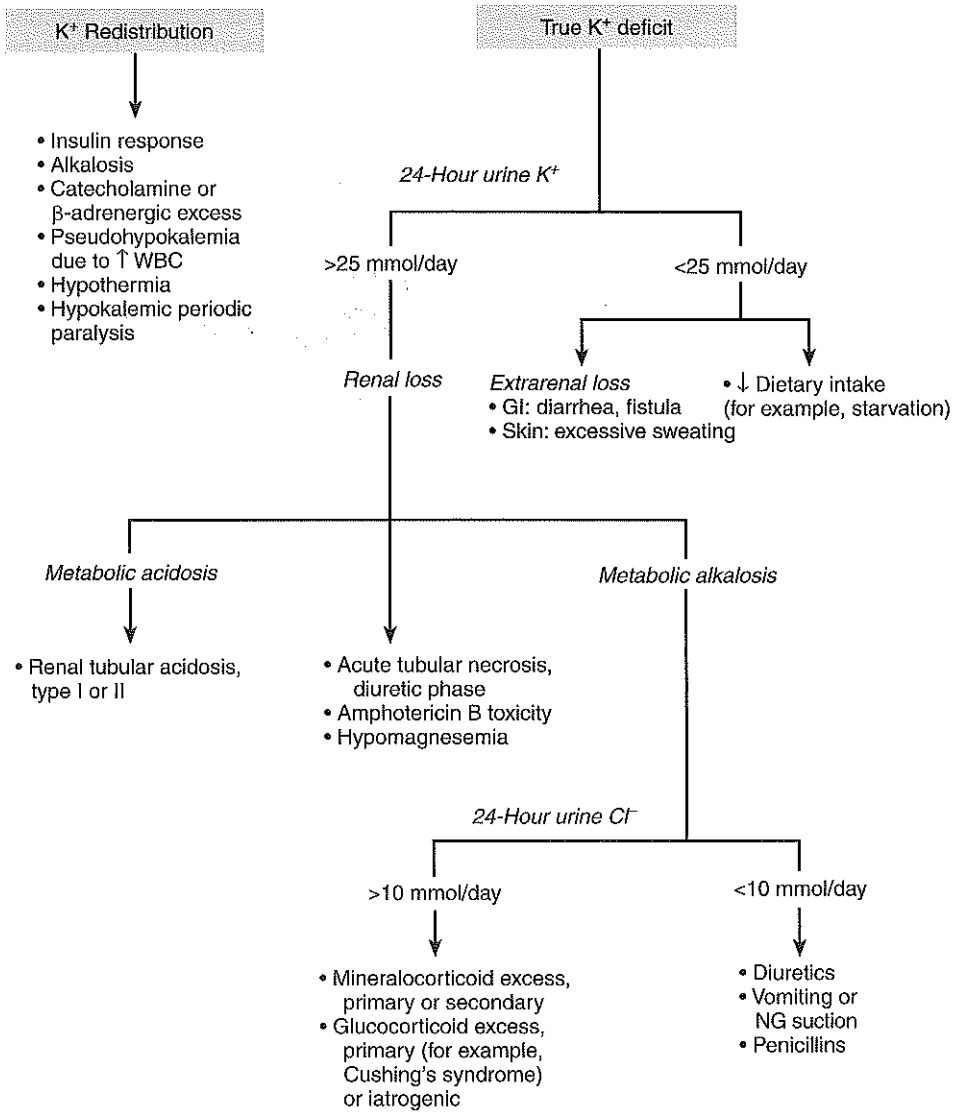

Figure 46-4 Algorithm for the differential diagnosis of hypokalemia. *(Modified from Kirkpatrick W, Kreisberg R. Acid-base and electrolyte disorders. In: Liu P, ed. Blue book of diagnostic tests. Philadelphia: WB Saunders Co, 1986:239-54.)*

deficits, as a result of either decreased intake or a loss of potassium-rich body fluids (Figure 46-4).

Redistribution

Intracellular redistribution of K^+ is illustrated by the fall in plasma K^+ that occurs following insulin therapy for diabetic hyperglycemia. The cells must take up K^+ as a consequence of glucose transport. Redistribution hypokalemia is also a feature of alkalosis, in which K^+ moves from ECF into the cells as H^+ moves in the opposite direction. In addition, the renal conservation of H^+ in the distal tubule occurs at the expense of K^+ ions. On the other hand, severe intracellular K^+ depletion may also *cause* alkalosis, as H^+ shifts intracellularly. Catecholamines and states of endogenous or pharmacological β-adrenergic excess have a similar effect. Pseudohypokalemia is a feature of acute leukemias. The elevated white blood cell count can cause a time-dependent transport of K^+ into the leukemic cells after the blood sample is drawn. Other less common causes of intracellular redistribution are listed in Figure 46-4.

True Potassium Deficit

Hypokalemia reflecting true total body deficits of K^+ can be classified into renal and nonrenal losses based on daily excretion of K^+ in the urine (see Figure 46-4). If urine excretion of K^+ is <30 mmol/day, it can be concluded that the kidneys are properly functioning and attempting to reabsorb as much K^+ as possible in the hypokalemic setting. Causes are either decreased K^+ intake or extrarenal loss of K^+-rich fluid. Situations of decreased intake include chronic starvation

and postoperative intravenous fluid therapy with K^+-poor solutions. Gastrointestinal loss of K^+ occurs most commonly with diarrhea.

Urine excretion exceeding 25 to 30 mmol/day in a hypokalemic setting is inappropriate and indicates that the kidneys are the primary source of lost K^+. Renal losses of K^+ may occur during the diuretic (recovery) phase of acute tubular necrosis and during states of excess mineralocorticoid (primary or secondary aldosteronism) or glucocorticoid (Cushing's syndrome) when the distal tubules increase Na^+ reabsorption and concurrently increase K^+ excretion. Renal loss of K^+ is also caused by thiazide and loop diuretics. It is noteworthy that certain diuretics (e.g., spironolactone) are "potassium sparing," because their mechanism of action inhibits aldosterone binding. Other causes of renal loss of K^+ include the use of carbenicillin, ticarcillin, or amphotericin.[16] In addition to redistribution of K^+ into cells in an alkalotic setting, K^+ can also be lost from the kidneys in exchange for reclaimed H^+ ions. This cause of true hypokalemia will be evident by low urine Cl^- and often an alkaline urine.

Hyperkalemia

Hyperkalemia (plasma $K^+ > 5.0$ mmol/L) is a result of (either singly or in combinations) (1) redistribution, (2) increased intake, or (3) increased retention. In addition, preanalytical conditions—such as hemolysis, thrombocytosis ($>10^6/\mu L$), and leukocytosis ($>10^5/\mu L$)—also have been known to cause marked pseudohyperkalemia as described in detail in Chapter 27 (Figure 46-5).

Redistribution

The transfer of intracellular K^+ into ECF invariably occurs in acidosis as H^+ shifts intracellularly and K^+ shifts outward to maintain electrical neutrality. As a general rule, K^+ concentrations are expected to rise 0.2 to 0.7 mmol/L for every 0.1 unit drop in pH. When the underlying cause of the acidosis is treated, normokalemia will rapidly be restored. Extracellular redistribution of K^+ may also occur in (1) dehydration, (2) shock with tissue hypoxia, (3) insulin deficiency (e.g., diabetic ketoacidosis), (4) massive intravascular or extracorporeal hemolysis, (5) severe burns, (6) tumor lysis syndrome, and (7) violent muscular activity, such as that occurring in status epilepticus. Finally, important iatrogenic causes of redistribution hyperkalemia include digoxin toxicity and β-adrenergic blockade, especially in patients with diabetes or on dialysis.[25]

Potassium Retention

When glomerular filtration or renal tubular function is decreased, hyperkalemia may be precipitated by intravenous infusion of K^+. Infusion rates in excess of 20 mmol/hr or use

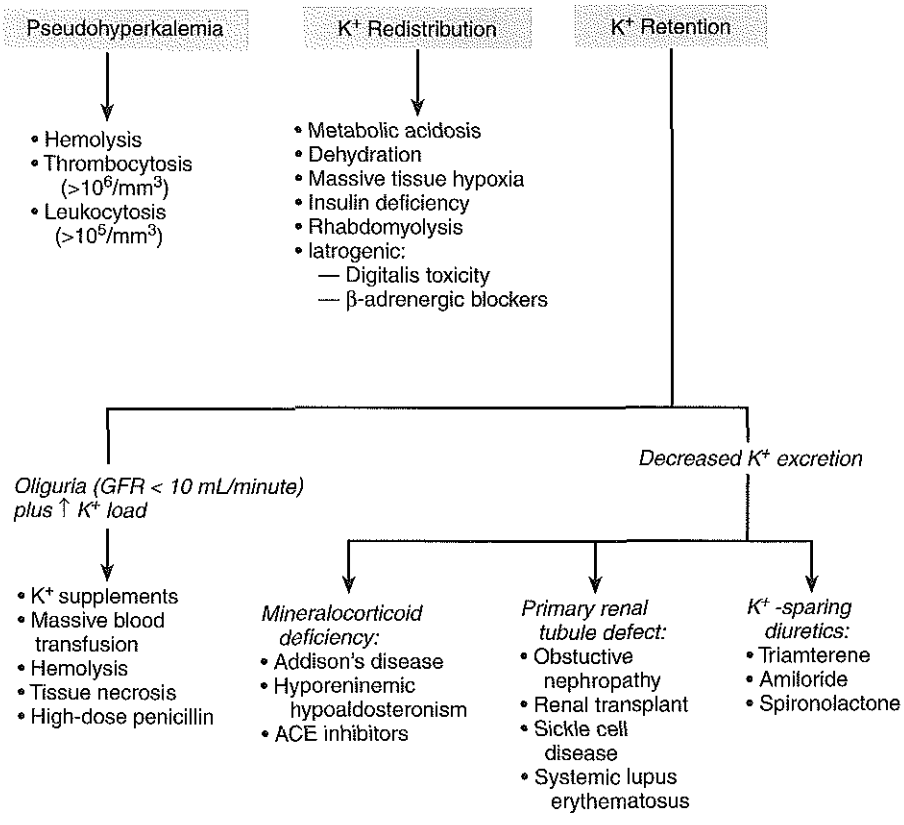

Figure 46-5 Algorithm for the differential diagnosis of hyperkalemia. *(Modified from Kirkpatrick W, Kreisberg R. Acid-base and electrolyte disorders. In: Liu P, ed. Blue book of diagnostic tests. Philadelphia: WB Saunders Co, 1986:239-54.)*

of K^+ solutions with concentrations greater than 40 mmol/L can be dangerous. When renal function is normal, overtreatment is unlikely to produce hyperkalemia because there is more than adequate renal capacity to excrete excess K^+. Indeed, in the absence of severe renal failure, hyperkalemia is seldom prolonged. Decreased excretion of K^+ in acute renal disease and end-stage renal failure (with oliguria or anuria and acidosis) are the most common causes of prolonged hyperkalemia (see Figure 46-5). Hyperkalemia occurs along with Na^+ depletion in adrenocortical insufficiency (e.g., Addison's disease) because diminished Na^+ reabsorption and concomitant decrease in Na^+-K^+ exchange results in decreased K^+ secretion. Drugs that block the production of aldosterone, such as the inhibitors of the angiotensin-converting enzyme ("ACE inhibitors," e.g., captopril) may also cause hyperkalemia. Other causes of hyperkalemia include salt-losing congenital adrenal hyperplasia and excess administration of potassium-sparing diuretics that block distal tubular K^+ secretion (e.g., triamterene and spironolactone).[12]

Chloride

The chloride (Cl^-) ion is the most abundant anion in the ECF (see Table 46-2). In the absence of acid-base disturbances, Cl^- concentrations in plasma will generally follow those of Na^+. However, determination of plasma Cl^- concentration is useful in the differential diagnoses of acid-base disturbances and is essential for calculating the anion gap (see Increased Anion Gap Acidosis [Organic Acidosis] section later in this chapter). Fluctuations in serum or plasma Cl^- have little clinical consequence, but do serve as signs of an underlying disturbance in fluid and acid-base homeostasis and can be an aid in differentiating the cause of these disturbances.

Hypochloremia

In general, causes of hypochloremia will parallel those causes of hyponatremia discussed earlier. Hypochloremia is frequently observed in metabolic acidoses that are caused by increased production or diminished excretion of organic acids (e.g., diabetic ketoacidosis and renal failure). In such cases, the fraction of total anion concentration represented by Cl^- is diminished because the complementary fraction of β-hydroxybutyrate, acetoacetate, lactate, and phosphate is increased. Persistent gastric secretion and prolonged vomiting, whatever the cause, result in significant loss of Cl^- and ultimately in a hypochloremic alkalosis and depletion of total body Cl^- with corresponding retention of HCO_3^-.

Hyperchloremia

Increased plasma Cl^- concentration, like increased Na^+ concentration, occurs with dehydration, RTA, acute renal failure, metabolic acidosis associated with prolonged diarrhea and loss of sodium bicarbonate, DI, states of adrenocortical hyperfunction, and overtreatment with saline solutions. A slight rise in Cl^- concentration may also be seen in respiratory alkalosis due to the renal compensation of excreting HCO_3^-. Hyperchloremic acidosis may be a sign of severe renal tubular disease.

Bicarbonate

Total carbon dioxide (CO_2) content of plasma consists of carbon dioxide dissolved in an aqueous solution (dCO_2), CO_2 loosely bound to amine groups in proteins (carbamino compounds), HCO_3^- and vanishingly small amounts of CO_3^{2-} ions, and carbonic acid (H_2CO_3). Bicarbonate ions make up all but ~2 mmol/L of the total carbon dioxide of plasma (22 to 31 mmol/L). Measurement of the total CO_2 as part of an electrolyte profile is useful chiefly to evaluate HCO_3^- concentration in assessment of acid-base disorders.

Alterations of HCO_3^- and CO_2 dissolved in plasma are characteristic of acid-base imbalance. Its value has most significance in the context of other electrolyte values and with blood gases and pH values. The full clinical significance of the determination of total CO_2 will become apparent in the following discussion of acid-base physiology.

ACID-BASE PHYSIOLOGY

The normal human diet is almost neutral, containing only a small amount of titratable acid. However, metabolic processes in the body result in the production of relatively large amounts of carbonic, sulfuric, phosphoric, and other acids. For example, during a 24-hour period, a person weighing 70 kg disposes of about 20 mol of carbon dioxide (the volatile form of carbonic acid) through the lungs and about 70 to 100 mmol (or ~1 mmol/kg) of titratable, nonvolatile acids (mainly sulfuric and phosphoric acids) through the kidneys. These products of metabolism are transported to the lungs and kidneys via the ECF and blood without producing any appreciable change in the plasma pH and with only a minimal pH difference between arterial (pH 7.35 to 7.45) and venous (pH 7.32 to 7.38) blood. This is accomplished by the buffering capacity of blood and by respiratory and renal regulatory mechanisms.

Acid-Base Balance and Acid-Base Status

A description of acid-base balance involves an accounting of the carbonic (H_2CO_3, HCO_3^-, CO_3^{2-}, and CO_2) and noncarbonic acids and conjugate bases in terms of input (intake plus metabolic production) and output (excretion plus metabolic conversion) over a given time interval. The acid-base status of the body fluids is typically assessed by measurements of total CO_2 plasma pH and PCO_2, because the bicarbonate/carbonic acid system is the most important buffering system of the plasma. Occasionally, measurement of total titratable acid or base, or other acid and base analytes (e.g., lactate and ammonia [NH_3]) is necessary to determine the etiology of an acid-base disorder.

The following clinical terms are used to describe the acid-base status. *Acidemia* is defined as an arterial blood pH <7.35 and *alkalemia* indicates an arterial blood pH >7.45. *Acidosis* and *alkalosis* refer to pathological states that lead to acidemia or alkalemia. For example, in common acid-base disorders

like lactic acidosis and diabetic ketoacidosis, intermediate organic acids (lactic acid and β-hydroxybutyric acid, respectively), which are normally metabolized to carbon dioxide and water, may accumulate to a significant extent, resulting in acidemia. Additionally, more than one type of pathological process can occur simultaneously, giving rise to a mixed acid-base disturbance, in which the blood pH may be low, high, or within the reference interval. These measurements reflect a static sampling of a dynamic process involving complex interactions between multiple buffering systems and the compensatory mechanisms of the kidneys and lungs. To understand how these and other perturbations of acid-base metabolism affect human physiology, it will be necessary to examine briefly, but carefully, the concepts of acids, bases, pH, and buffers in relation to the relevant systems that function to maintain normal acid-base balance in the human body.

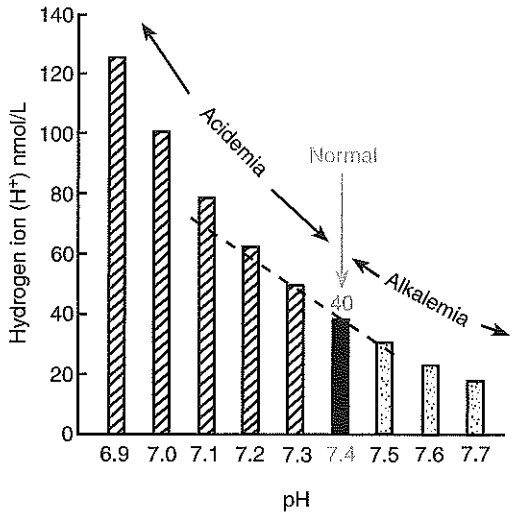

Figure 46-6 Relationship of pH to hydrogen ion concentration. **A,** *Broken line* is drawn to emphasize the (approximate) linear relationship between hydrogen ion concentration and pH over the pH range of 7.2 to 7.5. *(From Narins RG, Emmett M. Simple and mixed acid-base disorders: A practical approach. Medicine 1980;59:161-87.)* **B,** Scale for the interconversion of pH and hydrogen ion concentration.

Acid-Base Parameters—Definitions and Abbreviations

Acids are chemical substances that can donate protons (H^+ ions) in solution, and *bases* are substances that accept protons. Strong acids readily give up H^+, whereas strong bases readily accept H^+. Thus the conjugate base of a strong acid is a weak base and vice versa.

pH and pK

The pH of a solution is defined as the negative logarithm of the hydrogen ion activity ($pH = -\log aH^+$). Thus *pH is a dimensionless quantity,* such that a decrease of one pH unit represents a tenfold increase in the H^+ activity. The average pH of blood (7.40) corresponds to a hydrogen ion concentration of 4×10^{-8} mol/L = 40 nmol/L, but this assumes an activity coefficient of 1 (Figure 46-6). Potentiometric determinations of blood pH measure H^+ activity and not the H^+ concentration, although the activity is assumed to equal the concentration. The relationship between hydrogen ion activity and pH is illustrated in Figure 46-6. The relationship is inverse and obviously nonlinear. Many European centers express the acidity of blood in terms of its hydrogen ion concentration in nanomoles per liter (nmol/L). This form of expression has the advantage of avoiding logarithmic transformations when performing acid-base calculations. Even though it is consistent with how other ion concentrations are expressed, it has not gained widespread use in the United States.

The pK (also, pK' and pK_a) represents the negative logarithm of the ionization constant of a weak acid (K_a). That is, the pK is the pH at which an acid is half dissociated, existing as equal proportions of acid and conjugate base. Thus acids have pK values <7.0, whereas bases have pK values >7.0. The lower the pK, the stronger the acid, and the higher the pK, the stronger the conjugate base. For example, the pK of lactic acid is 3.5, and is 9.5 for the ammonium ion NH_4^+. The high pK for the ammonium ion indicates that this species prefers to hold onto its proton, rather than dissociating into NH_3 and H^+.

The pH of the plasma may be considered to be a function of two independent variables: (1) the PCO_2, which is regulated by the lungs and represents the acid component of the carbonic acid/bicarbonate buffer system, and (2) the concentration of titratable base (base excess or deficit, which is defined later), which is regulated by the kidneys. The plasma bicarbonate concentration is generally taken as a measure of the base excess or deficit in plasma and ECF, although it is recognized that conditions exist in which bicarbonate concentration may not accurately reflect the true base excess or deficit.

Bicarbonate and Dissolved CO_2

Bicarbonate is the second largest fraction (behind Cl^-) of plasma anions (~25 mmol/L). Conventionally, it is defined to include (1) plasma bicarbonate ion, (2) carbonate, and (3) CO_2 bound in plasma carbamino compounds (Figure 46-7). At the pH of blood, the plasma carbonate concentration is ~25 μmol/L, which is ~1/700 to 1/1000 of the total bicarbonate concentration. CO_2-bound carbamino compounds (RCNHCOOH) are 0.2 mmol/L in plasma and 1.5 mmol/L in erythrocytes. Actual bicarbonate ion concentration is not measured, but rather calculated from the Henderson-Hasselbalch equation as described below (and discussed in detail in Chapter 27). Also, as described in Chapter 27, the analyte usually measured in plasma is total CO_2, which includes bicarbonate and dissolved CO (dCO_2). The dCO_2 fraction is defined to include both the undissociated carbonic acid and physically dissolved, free CO_2. At the pH of the blood, the amount of dissolved CO_2 is 700 to 1000 times greater than the amount of carbonic acid and therefore

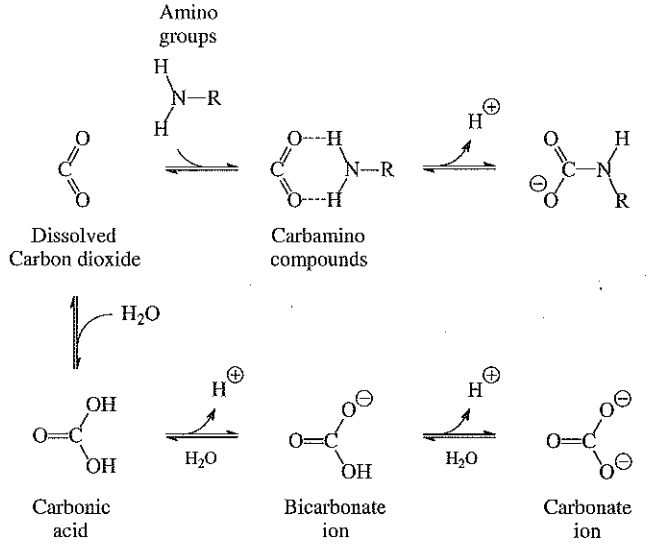

Figure 46-7 Reactions of CO_2 with water and amino groups. Hydrogen bonding is indicated by a dotted bond. The carbamino acid is fairly strong —R—NH—COOH → H^+ + R—NH—COO^-.

$cdCO_2$ is the term used to express their combined concentration. It is calculated from the solubility coefficient of CO_2 in blood at 37 °C ($\alpha = 0.0306$ mmol/L per mm Hg) multiplied by the measured PCO_2 in mm Hg. Thus at a PCO_2 of 40 mm Hg, $cdCO_2$ is 1.224 mmol/L (0.0306 mmol/L × 40 mm Hg). This $cdCO_2$ value can then be used, in the Henderson-Hasselbalch equation, to calculate the total bicarbonate concentration.

Henderson-Hasselbalch Equation

The Henderson-Hasselbalch equation is described in detail in Chapter 27. However, it is important to review this equation here because it aids in understanding pH regulation of body fluids as it relates to the compensatory mechanisms of the body in acid-base disturbances. The equation derived in Chapter 27 can also be written as follows:

$$\text{pH} = 6.1 + \log\frac{c\text{HCO}_3^-}{cd\text{CO}_2}$$

where $cdCO_2$ is equal to α (0.0306 mmol/L per mm Hg) × PCO_2 and 6.1 is the apparent pK' for the carbonic acid/bicarbonate system (see Chapter 27). An alternative expression useful for approximating cH^+ in blood is:

$$c\text{H}^+ = K \times \frac{P\text{CO}_2}{c\text{HCO}_3^-}$$

where $K = 24$ (nmol/L) × (mmol/L) × (mm Hg^{-1}).

The average normal ratio of the concentrations of bicarbonate and dissolved carbon dioxide in plasma is 25 (mmolL)/1.25 (mmol/L) = 20/1. It follows then that any change in the concentration of either bicarbonate or dissolved CO_2 must be accompanied by a change in pH. Such changes in the ratio can occur through a change either in the numerator (the renal component) or in the denominator (the respiratory component). Clinical conditions characterized as *metabolic* disturbances of acid-base balance are classified as primary disturbances in $cHCO_3^-$. Those characterized as *respiratory* disturbances are classified as primary disturbances in $cdCO_2$. Various compensatory mechanisms attempting to reestablish the normal ratio of $cHCO_3^-/cdCO_2$ may result in changes in the bicarbonate concentration, dissolved CO_2 concentration, or both. The application of the Henderson-Hasselbalch equation to human acid-base physiology can be illustrated by a lever-fulcrum (teeter-totter) diagram (Figure 46-8).

Buffer Systems and Their Role in Regulating the pH of Body Fluids

A buffer is a mixture of a weak acid and a salt of its conjugate base that resists changes in pH when a strong acid or base is added to the solution (see Chapter 1). If the concentrations of the acid and base components of a buffer are equal, the pH will equal the pK. Generally, buffers work best at resisting changes in pH in the interval ± one pH unit of its pK. That is, buffers work best when the ratio of acid : base is within the range of 10:1 to 1:10. Buffers are also more effective at higher concentrations, so that a 10 mmol/L buffer solution is more effective than a 1.0 mmol/L solution.

The action of buffers in the regulation of body pH can be explained by using the bicarbonate buffer system as an example. If a strong acid is added to a solution containing HCO_3^- and H_2CO_3, the H^+ will react with HCO_3^- to form more H_2CO_3 and subsequently CO_2 and H_2O. The hydrogen ions are thereby bound, and the increase in the H^+ concentration will be minimal.

$$\text{HCO}_3^- + \text{H}^+ \rightarrow \text{H}_2\text{CO}_3 \rightarrow \text{CO}_2 + \text{H}_2\text{O}$$

The buffer systems of most physiological interest in connection with regulation of the pH of body fluids are those of plasma and erythrocytes. Discussions of the most important physiological buffers follow.

Bicarbonate/Carbonic Acid Buffer System

The most important buffer of plasma is the bicarbonate/carbonic acid pair. Initially, one might not think that this buffer would be very effective because its pK is 6.1, whereas normal plasma pH is 7.4. Furthermore, the ratio of base to acid is ~20:1 in plasma, which is outside the general limits for good buffering capacity. However, the effectiveness of the bicarbonate buffer is based on its high concentration (>20 mmol/L) and on the fact that the lungs can readily dispose of or retain CO_2. In addition, the renal tubules can increase or decrease the rate of reclamation of bicarbonate from the glomerular filtrate (see Chapter 45). The importance of the high concentration becomes apparent when one considers that at normal pH, 5 mmol/L of lactate (pK ~4) generates ~5 *mmol/L* of H^+ ion, which is remarkable considering that a normal H^+ ion concentration is only 40 nmol/L.

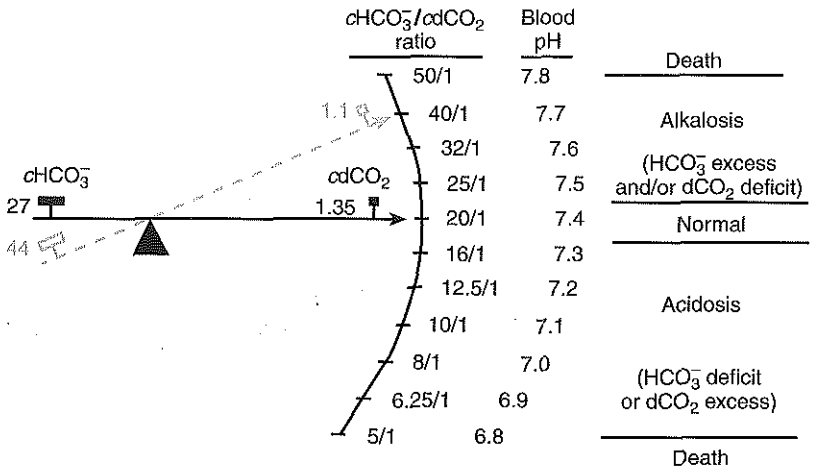

Figure 46-8 Scheme demonstrating the relation between pH and ratio of bicarbonate concentration to the concentration of dissolved CO_2. If the ratio in blood is 20:1 ($cHCO_3^- = 27$ mmol/$cdCO_2 = 1.35$ mmol/L), the resultant pH will be 7.4 as demonstrated by the *solid beam*. The *dotted line* shows a case of uncompensated alkalosis (bicarbonate excess) with a bicarbonate concentration of 44 mmol/L and a $cdCO_2$ of 1.1 mmol/L. The ratio therefore is 40:1, and the resultant pH is 7.7. In a case of uncompensated acidosis, the pointer of the balance would point to a pH between 6.8 and 7.35, depending on the $cHCO_3^-/cdCO_2$ ratio. *(From Weisberg HF. A better understanding of anion-cation ("acid-base") balance. Surg Clin North Amer 1959;39:93-120; Snively WD, Wessner M. ABC's of fluid balance. J Ind State Med Assoc 1954;47:957-72.)*

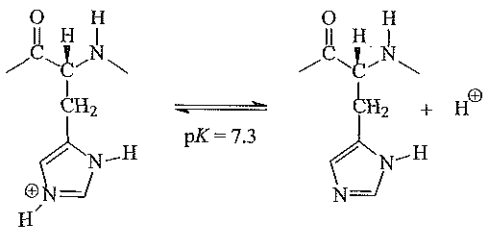
Other nonbicarbonate buffers of blood are present at <10 mmol/L concentration.

The buffer value (β) is defined as the amount of base required to cause a change in pH of one unit. The buffer value of the bicarbonate buffer in plasma is 55.6 mmol/L. Derivation of this value is obtained by taking partial differentials of the Henderson-Hasselbalch equation, which is presented in detail in the second edition of this textbook.[30]

Phosphate Buffer System

At a plasma pH of 7.4, the ratio $cHPO_4^{2-}/cH_2PO_4^-$ is 4/1 ($pK' = 6.8$). The total concentration of this buffer in both erythrocytes and plasma is less than that of other major buffer systems, accounting for only about 5% of the nonbicarbonate buffer value of plasma. Organic phosphate, however, in the form of 2,3-diphosphoglycerate (present in erythrocytes in a concentration of about 4.5 mmol/L), accounts for about 16% of the nonbicarbonate buffer value of erythrocyte fluid.

The phosphate buffer reacts with acids and with bases as follows:



$$HPO_4^{\oplus\oplus} + H^{\oplus} \longrightarrow H_2PO_4^{\oplus}$$

$$H_2PO_4^{\oplus} + OH^{\ominus} \longrightarrow HPO_4^{\oplus\oplus} + H_2O$$

This system is important in the excretion of acids in the urine, as is explained in the section on renal compensatory mechanisms.

Plasma Protein Buffer System and Plasma Base Excess

The buffer value (β) of the nonbicarbonate buffers of plasma is about 7.7 mmol/L at pH 7.40 and a normal plasma protein concentration of 72 g/L. Proteins, especially albumin, account for the greatest portion (95%) of the nonbicarbonate buffer value of the plasma. The most important buffer groups of proteins in the physiological pH range are the imidazole groups of histidines (pK ~7.3). Each albumin molecule contains 16 histidines.

The significance of the nonbicarbonate buffers of the plasma can be illustrated when considering the chemical reactions during CO_2 equilibration:

$$CO_2 + H_2O \longrightarrow H_2CO_3 \longrightarrow HCO_3^{\ominus} + H^{\oplus}$$

$$HPr \longleftarrow H^{\oplus} + Pr^{\ominus}$$

where the HPr/Pr^- system represents all nonbicarbonate buffers. Since the purpose of this buffer system is to maintain cH^+ constant, for each molecule of HCO_3^- that is gener-

ated, one molecule of nonbicarbonate buffer base disappears. Thus in alkalosis, the cH^+ from CO_2 equilibration falls and there is a resulting excess of nonbicarbonate buffer base. As follows, there is a consumption or negative excess of this buffer base in acidosis.

Plasma base excess is defined as the initial concentration of titratable base when titrating the plasma with strong acid or base to pH (Std) = 7.4 at PCO_2 = 40 mm Hg and 37 °C. The equation for the CO_2 equilibration curve of plasma and calculation of *plasma base excess* can be written:

$$\Delta cHCO_3^-(P) = [-\beta Pr \times \Delta pH(P)] + \Delta cB'(P)$$

where $\Delta cHCO_3^-$ = actual HCO_3^- minus the standard HCO_3^- of 24.5 mmol/L, ΔpH = measured pH minus 7.40, and $\Delta cB'(P)$ is the plasma base excess.

Hemoglobin Buffer System and Whole Blood Base Excess

The buffer value (β) of the nonbicarbonate buffers of erythrocyte fluid is about 63 mmol/L at pH 7.20 for an erythrocyte hemoglobin (Fe) concentration of 21 mmol/L (33.8 g/dL). Hemoglobin accounts for the major part (53 mmol/L), with the remainder being mainly caused by 2,3-diphosphoglycerate (2,3-DPG). The imidazole groups of hemoglobin are quantitatively the most important buffer groups.

As in plasma, CO_2 equilibration of whole blood depends on the buffer value of nonbicarbonate buffers. Thus CO_2 equilibration in whole blood is dependent on hemoglobin concentration and also on pH and oxygenation status. It is possible to derive an approximate equation for whole blood CO_2 equilibration and calculation of *whole blood base excess* as follows:

$$\Delta cHCO_3^-(P) = -\beta \times \Delta pH(P) + \frac{\Delta cB'(B)}{\zeta}$$

where

$\Delta cHCO_3^-$ = measured plasma $cHCO_3^-(P)$ − 24.5 mmol/L HCO_3^-

ΔpH = measured pH − the standard pH of 7.40

$\Delta cB'(B)$ = the *whole blood base excess* (i.e., the concentration of titratable base when titrating the blood with strong acid or base to pH = 7.40 at PCO_2 [Std] and 37 °C)

$\beta = \beta_m Hb \times cHb(B) + \beta Pr$, where $\beta_m Hb$ is the molar buffer value of hemoglobin (2.3 mol/mol), $cHb(B)$ is the substance concentration of hemoglobin (Fe) in the blood (unit: mmol/L), and βPr is the buffer value of the plasma proteins (7.7 mmolL)

$\zeta = 1 - cHb(B)/c_{ref}$, where c_{ref} is an empirical parameter (43 mmol/L)

This equation for *whole blood base excess* (known as the Van Slyke equation[22,23]), together with the Henderson-Hasselbalch equation, provides the simplest algorithm for calculation of the various acid-base variables. The buffer value of HHb is slightly lower than that for O_2Hb at pH ~6.5 but higher at pH ~7.8. This is due to a decrease in the pK value of the "oxygen-linked" acid-base groups of Hb (C-terminal histidine and N-terminal valine) when HHb is oxygenated. When oxygenated, H^+ ions are liberated from Hb, a phenomenon called the *Haldane effect*. In a hemoglobin solution, a close relationship exists between the Bohr effect (the effect of pH on the O_2 saturation, see Chapter 27) and the Haldane effect. However, for whole blood, the rise in the concentration of titratable base, known as the Haldane coefficient for whole blood ($\Delta cB'[B]$), is only 0.3 mmol/L when oxyhemoglobin at a concentration of 1 mmol/L is converted to deoxyhemoglobin. For more detail of the interaction of the Bohr and Haldane effects, see Chapter 31 of the second edition of this textbook.[30]

Isohydric and Chloride Shift

Because of the continuous production of carbon dioxide within tissue cells, there is a concentration gradient for carbon dioxide from cells to the plasma and thus to erythrocytes. Despite this, the combination of all the buffer systems discussed previously interacts together with the Haldane effect in a phenomenon known as the isohydric Cl^- shift, which keeps the $cdCO_2$ and cH^+ (pH) essentially constant between arterial and venous blood. A small portion of the carbon dioxide entering the plasma stays as dissolved carbon dioxide, thus the slightly higher PCO_2 in venous blood. The majority reacts with water to form carbonic acid that dissociates into H^+ and HCO_3^-. The increased amount of H^+ is buffered by plasma buffers (Figure 46-9, reaction 1). Another small portion combines with the amino groups of proteins and forms carbamino compounds (Figure 46-9, reaction 2). The normal concentration of carbamino compounds in the plasma is about 0.2 mmol/L. Most of the carbon dioxide enters the erythrocytes and reacts with water to form carbonic acid. This reaction is catalyzed by the enzyme carbonic anhydrase (CA) and proceeds at a relatively high rate (Figure 46-9, reaction 3). Some CO_2 remains as dissolved CO_2 and some combines with Hb to form $HbCO_2$ (Figure 46-9, reaction 4).

The carbonic acid formed in reaction 3 initially increases the H^+ concentration. The pH change, however, is fully or partially compensated by the release of oxygen from O_2Hb, which involves the conversion of the stronger acid (O_2Hb) into a weaker acid (HHb) that then readily accepts the H^+. For each mole of O_2 released, the hemoglobin binds about 0.5 mol of H^+ ion. Furthermore, the HHb binds significantly more CO_2 in the form of carbamino-CO_2 than does oxyhemoglobin; thus an additional fraction of CO_2 is transported in this form. The oxygen released from O_2Hb moves from the erythrocytes through the plasma into the peripheral tissue cells.

The remainder of the hydrogen ions formed in reaction 3 are buffered by the nonbicarbonate buffers of the erythrocyte fluid, whereas the concentration of HCO_3^- increases to the same extent that the concentration of Hb anion falls.

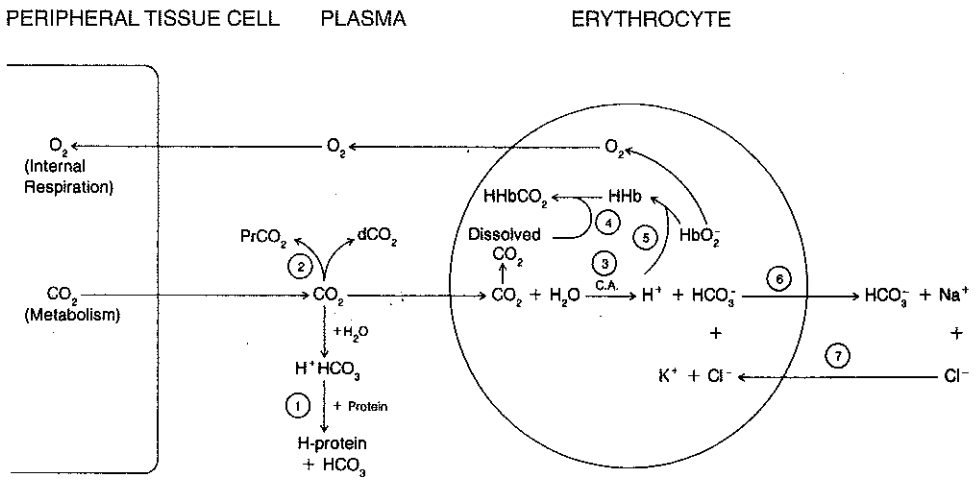


Figure 46-9 Scheme demonstrating the isohydric and chloride shift. The *encircled numbers* refer to the reactions described in the text. For details, see text.

The transformations described so far (Figure 46-9, reactions 1 through 5) are referred to as the *isohydric shift* (i.e., a shift in which the hydrogen ion concentration remains unchanged).

The equilibrium between plasma and red cells has been disturbed by the reactions described so far. The concentration of HCO_3^- has increased relatively more in the erythrocytes than in the plasma; the pH of plasma has fallen relatively more than the pH of the erythrocytes; and the nondiffusible ion concentration in the erythrocytes has fallen because of the increase in protonation of proteins and hemoglobin. The membrane potential of the erythrocytes therefore becomes less negative, and the distribution of all diffusible ions must change in accordance with the new membrane potential. The ion shifts that occur rapidly are a movement of HCO_3^- out of the erythrocytes and a movement of Cl^- into the erythrocytes to provide electrochemical balance. This shift of chloride ions is referred to as the *chloride shift* (Figure 46-9, reactions 6 and 7). As a result of these ion fluxes, the concentration of chloride in the venous plasma is about 1 mmol/L lower than that in the arterial plasma.

The HCO_3^-, the carbamino compounds, and the dissolved carbon dioxide are transported in venous blood to the pulmonary capillaries and alveoli. The comparatively low PCO_2 in the alveoli will cause a shift of carbon dioxide from the erythrocytes and the plasma into the alveoli. On the other hand, the high PO_2 in the alveoli causes a shift of oxygen into the plasma and the erythrocytes. This exchange causes a reversal of reactions 1 through 7 in Figure 46-9.

Respiratory Mechanism in the Regulation of Acid-Base Balance

In addition to supplying O_2 to tissue cells for normal metabolism, the respiratory mechanism contributes to the maintenance of normal body pH through elimination or retention of CO_2 in metabolic acidosis and alkalosis, respectively.

Respiration

Exchange of O_2 and CO_2 in the lungs between alveolar air and blood is called *external respiration*, in contrast to internal respiration occurring at the tissue level. At inspiration, contraction of the diaphragm and thoracic musculature expands intrathoracic volume and creates a fall in intrapulmonary pressure. Atmospheric air is drawn into the bronchial tree, which terminates at the alveoli. Alveoli are small saclike chambers with very thin walls in close approximation to pulmonary capillaries where the exchange of gases between alveolar air and pulmonary blood occurs. Expiration takes place passively by recoil as the elastic tissues of the lungs and chest wall rebound and the intrathoracic volume is decreased. Loss of elasticity of the lungs and destruction of the alveolar membranes are basic pathological mechanisms underlying many pulmonary diseases.

Peripheral venous blood reaches the pulmonary circulation from the right ventricle of the heart and is "arterialized" in the capillaries of the lungs by uptake of O_2 and loss of CO_2. Pulmonary venous blood then returns to the left ventricle by way of the left atrium and is pumped through the aorta to the peripheral tissues. In the capillaries of peripheral tissues, the arterial blood releases O_2 to the tissue cells and takes up CO_2. With return of blood to the lungs, the cycle is completed.

In a resting state, the respiration rate is normally 12 to 15 breaths/min. For an average-sized adult with a tidal volume (the amount of air exchanged per breath cycle) of about 0.5 L, 6 to 8 L of air is moved per minute in either direction. Physical activity increases ventilation (respiratory rate × tidal volume), i.e., the amount of air exchanged per minute. Voluntary efforts can increase the rate of ventilation 20 to 30 times over the resting concentration, but only briefly. Invol-

untary increases in rate and depth of respiration are regulated by the medullary respiratory center in the brain stem, which in turn is stimulated by central chemoreceptors located on the anterior surface of the medulla oblongata and by peripheral chemoreceptors located in the carotid arteries and aorta. Peripheral chemoreceptors are stimulated by a fall in pH caused by accumulation of CO_2 or by a decrease in PO_2. The central chemoreceptors are stimulated only by a decrease in pH of the CSF.

Often a patient's normal response to these chemical receptors that drive respiration is perturbed by a pathological condition in the circulatory or respiratory system. If significantly abnormal, the patient will require assisted ventilation that uses a mechanical device to provide gas mixtures intermittently via an endotracheal tube inserted through the mouth or through a tracheostomy. Gas mixtures containing different fractional compositions of O_2 and CO_2 may be administered in conjunction with assisted ventilation. A physician's adjustments of the conditions of this mechanical ventilation depend greatly on the results of blood gas and pH determinations that reflect current acid-base status.

Exchange of Gases in the Lungs and Peripheral Tissues

Diffusion of O_2 and CO_2 across alveolar and cell membranes is governed by gradients in the partial pressure of each gas (Figure 46-10). Dry air inspired at a pressure of 1 atm (760 mm Hg) consists of 21% O_2 (PO_2 ~160 mm Hg), 0.03% CO_2 (PCO_2 ~0.25 mm Hg), 78% nitrogen, and ~0.1% other inert gases. As inspired air passes over the moist mucous membranes of the upper respiratory tract, it is warmed to 37 °C, becomes saturated with water vapor, and mixes with air in the respiratory tree, resulting in partial pressures of ~150 mm Hg for O_2, 0.3 mm Hg for CO_2, ~47 mm Hg for H_2O, and 563 mm Hg for nitrogen. Further mixing with alveolar air results in partial pressures at the alveolar membrane of ~105 mm Hg for O_2, ~40 mm Hg for CO_2, and ~47 mm Hg for H_2O. Venous blood on the opposite side of the alveolar membrane contains O_2 at a partial pressure of approximately 40 mm Hg and CO_2 at approximately 46 mm Hg. Thus the gradient for O_2 is inward, toward the blood, and for CO_2, it is outward, toward the alveoli. CO_2 removal is so efficient that the PCO_2 in expired air is more than 100 times the PCO_2 in inspired air (see Figure 46-10). In the arterial blood, the PO_2 is slightly lower than in alveolar air (90 versus 105 mm Hg). This difference is due to shunting about 5% of blood through the lungs that does not equilibrate with O_2.

At the arterial end of capillaries of peripheral tissues, the PO_2 at approximately 90 mm Hg is substantially higher than the average PO_2 at the surface of the tissue cells (20 mm Hg), and the PCO_2 at ~40 mm Hg is substantially lower than that in the cells (50 to 70 mm Hg). Thus in the tissue capillary, the gradient for O_2 is inward to the cell; for CO_2 it is outward to the capillary blood. The arteriovenous difference in partial pressures is approximately 60 mm Hg for O_2 and 6 mm Hg or less for CO_2. This difference in arteriovenous PO_2 is one indicator of the efficiency of O_2 extraction in the passage of blood through the capillaries. During passage through the tissues, the concentration of total oxygen falls on average 2.3 mmol/L, whereas the concentration of total CO_2 of the blood rises about 2.0 mmol/L.

Respiratory Response to Acid-Base Perturbations

Most metabolic acid-base disorders develop slowly, within hours in diabetic ketoacidosis and months or even years in chronic renal disease. The respiratory system responds immediately to a change in acid-base status, but several hours may be required for the response to become maximal. The maximum response is not attained until both the central and peripheral chemoreceptors are fully stimulated. For example, in the early stages of metabolic acidosis, plasma pH decreases, but because H^+ ions equilibrate rather slowly across the blood-brain barrier, the pH in CSF remains nearly normal. However, because peripheral chemoreceptors are stimulated by the decreased plasma pH, hyperventilation occurs, and plasma PCO_2 decreases. When this occurs, the PCO_2 of the CSF decreases immediately because CO_2 equilibrates rapidly across the blood-brain barrier, leading to a rise in the pH of the CSF. This will inhibit the central chemoreceptors. But as plasma bicarbonate gradually falls because of acidosis, bicarbonate concentration and pH in the CSF will also fall over several hours. At this point, stimulation of respiration becomes maximal as both the central and peripheral chemoreceptors are maximally stimulated.

The reverse is true when a patient with metabolic acidosis is treated with HCO_3^-. When the pH in plasma increases as the result of HCO_3^- administration, stimulation of the peripheral chemoreceptors returns to normal. However, because of the slow equilibration of HCO_3^- between plasma and CSF, the central chemoreceptors continue to be stimulated, and the patient continues to hyperventilate, even when the blood pH has returned to normal. Respiration does not return to normal until normal acid-base balance in the CSF of the brain is restored.

Renal Mechanisms in the Regulation of Acid-Base Balance

The average pH of plasma and of the glomerular filtrate is ~7.4, whereas the average urinary pH is ~6.0, reflecting the renal excretion of nonvolatile acids produced by metabolic processes. The various functions of the kidneys respond to different alterations of acid-base status. In the case of acidosis, excretion of acids is increased and base is conserved; in alkalosis, the opposite occurs. The pH of the urine changes correspondingly and may vary in *random* specimens from pH 4.5 to 8.0. This ability to excrete variable amounts of acid or base makes the kidney the final defense mechanism against changes in body pH.

The various acids produced during metabolic processes are buffered in the ECF at the expense of HCO_3^-. Renal excre-

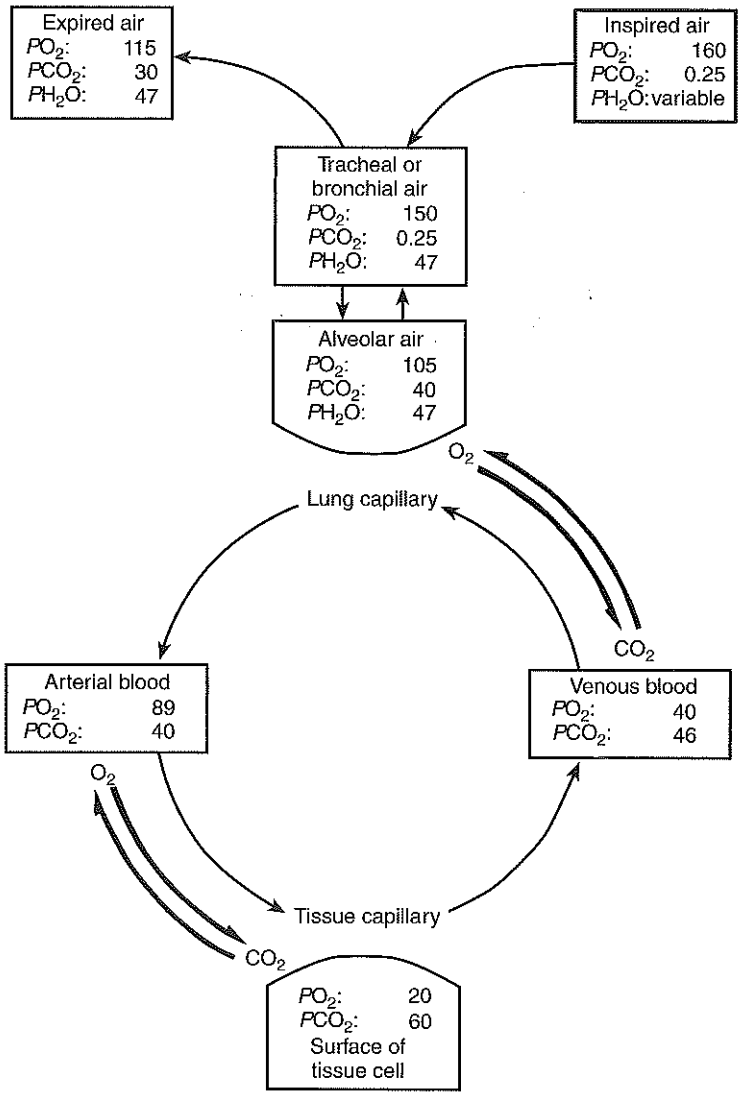

Figure 46-10 Partial pressures of oxygen and carbon dioxide in air, blood, and tissue. Values shown are approximations in mm Hg and calculated assuming a 5% shunt. *Heavy arrows* show directions of gradients. *(Modified from Tietz NW. Fundamentals of clinical chemistry, 3rd ed. Philadelphia: WB Saunders Co, 1987.)*

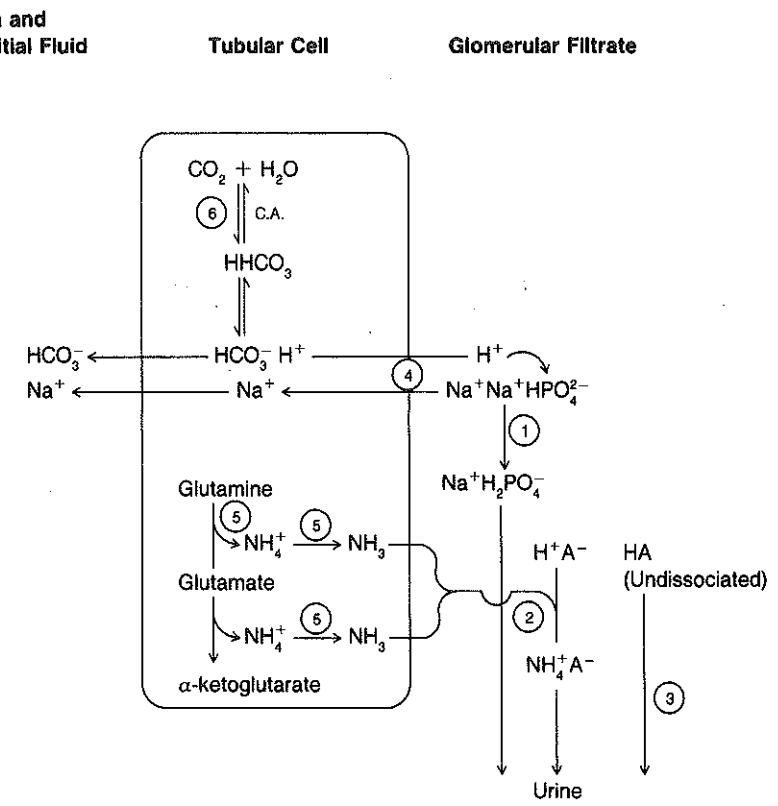
tion of acid and conservation of HCO_3^- occur through several mechanisms including (1) the Na^+-H^+ exchange, (2) production of ammonia and excretion of NH_4^+, and (3) reclamation of HCO_3^-.

Na^+-H^+ Exchange

Nearly all mammalian cells contain a plasma membrane ATP-hydrolyzing protein capable of exchanging sodium ions for protons—the so-called Na^+-H^+ exchanger (Figure 46-11). In 2002 it was reported that at least six isoforms of the Na^+-H^+ exchanger (NHE-1 through NHE-6) are differentially expressed in a wide variety of tissues.[18] These NHE isoforms exhibit 20% to 60% amino acid identity, with highly conserved transmembrane domains, suggesting that these domains are the sites of Na^+ and H^+ translocation.[18] In the renal tubules, NHE-1 and NHE-3 appear to be the predominant isoforms that extrude H^+ ions into the tubular fluid in exchange for Na^+ ions.

Na^+-H^+ exchange is enhanced in states of acidoses and inhibited in alkalotic states. Both NHE-1 and NHE-3 isoforms are transcriptionally upregulated in response to acidotic states. Additionally the NHE-3 isoform shows an increased V_{max} of Na^+-H^+ exchange during acidoses—a process that may be regulated by increased phosphorylation of the cytoplasmic domain. The proximal tubules, however, cannot maintain an H^+-gradient of more than ~1 pH unit whereas the distal tubules cannot maintain one of more than ~3 pH units. Thus maximum urine acidity is reached at ~pH 4.4. In Type I and Type IV RTA, this exchange process is defective and may lead to a decrease in blood pH. In Type I RTA, there is often an increase in urinary pH, but in Type IV, an additional defect in NH_3 excretion can result in normal or even decreased urine pH. Hydrogen ions of the glomerular filtrate, or those that have been transported through the Na^+-H^+ exchanger into the tubular fluid, may react with NH_3 or HPO_4^{2-} as shown in Figure 46-11 and described in the next section.



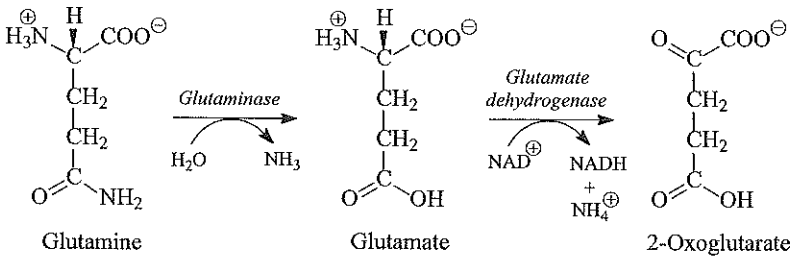


Figure 46-11 Hydrogen ion excretion, sodium hydrogen ion exchange, and ammonia production in the renal tubules. Key: *1*, conversion of HPO_4^{2-} to H_2PO_4; *2*, reaction of hydrogen ions with NH_3; *3*, excretion of undissociated acids; *4*, Na^+-H^+ exchange; *5*, NH_3 production; and *6*, synthesis of carbonic acid from CO_2.

Potassium ions compete with hydrogen ions in the renal tubular Na^+-H^+ exchanger. If the intracellular K^+ level of renal tubular cells is high, more K^+ and less H^+ are exchanged for Na^+. As a result, the urine becomes less acidic, thereby increasing the acidity of body fluids. If K^+ is depleted, more H^+ ions are exchanged for Na^+, and the urine becomes more acidic and the body fluids more alkaline. Thus hyperkalemia contributes to acidosis and hypokalemia to alkalosis. Because the body's compensatory mechanism against metabolic alkalosis is relatively ineffective, K^+ depletion alone can result in a metabolic alkalosis.

Renal Production of Ammonia and Excretion of Ammonium Ions

Renal tubular cells are able to generate ammonia from glutamine and other amino acids derived from muscle and liver cells according to the following reaction:

$$NH_4^+ \rightleftharpoons NH_3 + H^+$$

The ammonium ion produced dissociates into ammonia and hydrogen ions to a degree dependent on the pH (see Figure 46-11). At normal blood pH, the ratio of NH_4^+ to NH_3 is about 100 to 1. Ammonia is a gas and diffuses readily across the cell membrane into the tubular lumen, where it combines with hydrogen ions to form ammonium ions (see Figure 46-11). At the acid pH of urine, the equilibrium between NH_4^+ and NH_3 shifts markedly to the left (~10,000 to 1), strongly favoring formation of NH_4^+. The NH_4^+ formed in the tubular lumen cannot easily cross cell membranes

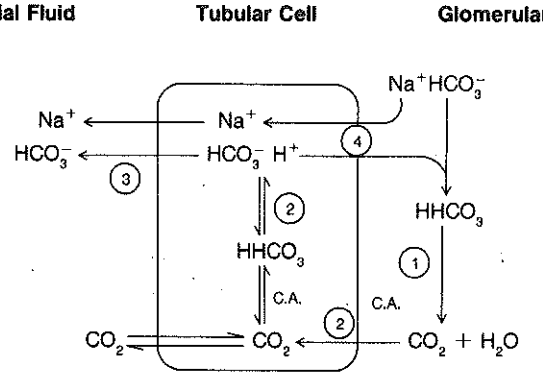

Figure 46-12 Key: *1*, Formation of CO_2 from bicarbonate in the tubular fluid; *2*, formation of H^+ and HCO_3^- from CO_2 in the tubular cell; *3*, new generation of HCO_3^-; and *4*, Na^+-H^+ exchange.

and thus is trapped in the tubular urine and excreted with anions such as phosphate, chloride, or sulfate. In normal individuals, NH_4^+ production in the tubular lumen accounts for the excretion of ~60% (30 to 60 mmol) of the hydrogen ions associated with nonvolatile acids. Finally the 2-oxoglutarate produced in this reaction is converted to bicarbonate (up to 270 mmol/day) that helps to replenish bicarbonate neutralized by metabolic acid production.

The amount of H^+ excreted bound to NH_3 can be measured as NH_4^+. The H^+ required for NH_4^+ formation may be present in the glomerular filtrate or may be generated within tubular cells by carbonic anhydrase synthesis of carbonic acid from CO_2 (see Figures 46-11 and 46-12). These hydrogen ions are secreted into the tubular lumen through the Na^+-H^+ exchangers (see Figure 46-11). In systemic acidosis, excretion accounts by far for the greatest net excretion of H^+ by the kidneys. However, the maximum rate of glutamine release and therefore of NH_3 production (~400 mmol/day) is not achieved until acidosis has persisted for 3 days. In patients with chronic Type IV RTA or with renal insufficiency, the kidneys are unable to generate sufficient NH_3 to buffer the nonvolatile acids produced, and this defect contributes significantly to the acidosis in such patients.

Excretion of H^+ as $H_2PO_4^-$

H^+ secreted into the tubular lumen by the Na^+-H^+ exchanger may also react with HPO_4^{2-} to form $H_2PO_4^-$ (see Figure 46-11). This process depends on the amount of phosphate filtered by the glomeruli and the pH of urine. Under normal physiological conditions, ~30 mmol of H^+ is excreted per day as $H_2PO_4^-$, and this amount accounts for ~90% of the titratable acidity of urine. In case of high-protein intake, phosphate production and filtration may be increased. Acidemia increases phosphate excretion and thus provides additional buffer for reaction with H^+. A decrease in the glomerular filtration rate (GFR), as observed in renal disease, may result in a decrease of $H_2PO_4^-$ excretion.

The secretion of H^+ and the subsequent reaction with $H_2PO_4^-$ allow the removal of one H^+ without any significant decrease in urinary pH. As a result, the pH gradient is not greatly affected and more H^+ can be secreted into the tubules, whereas more Na^+ is reabsorbed and conserved. The HCO_3^- formed by the action of carbonic anhydrase in the tubular cells in the process of H^+ secretion reclaims the HCO_3^- lost in buffering the body burden of ingested or produced acid.

Excretion of Other Acids

Strong acids, such as sulfuric, hydrochloric, and phosphoric, are fully ionized at the pH of urine and are excreted only after the H^+ derived from these acids reacts with a buffer base. Excretion of the anions of these acids is accompanied by the simultaneous removal of an equal number of cations, such as Na^+, K^+, or NH_4^+, to provide electrochemical balance. However, some acids, such as acetoacetic acid ($pK = 3.58$) and β-hydroxybutyric acid ($pK = 4.7$), are present in blood almost entirely in ionized form; at the acid pH frequently prevailing in urine, some are nondissociated and thus may be excreted partially as the nondissociated acid (see Figure 46-11). For example, 50% of β-hydroxybutyric acid at pH 4.7 is nonionized.

Reclamation of Filtered Bicarbonate

The unmodified glomerular filtrate has the same concentration of HCO_3^- as does plasma; however, with increasing acidification of the proximal tubular urine, the HCO_3^- concentration decreases. It is believed that these changes are triggered by the excretion of H^+ by the Na^+-H^+ exchanger mechanism, which results in a decrease in urinary pH. The H^+ excreted reacts with HCO_3^- (catalyzed by carbonic anhydrase, in the brush border of the proximal tubular cells) to form H_2CO_3 and subsequently CO_2 and H_2O (see Figure 46-12).

This increase in urinary CO_2 causes carbon dioxide to diffuse across the tubular wall into the tubular cell, where it

reacts with H_2O in the presence of *cytoplasmic* carbonic anhydrase in the tubular cells to form H_2CO_3 and subsequently H^+ and HCO_3^- (see Figure 46-12). Thus reclamation of bicarbonate is in fact diffusion of CO_2 into tubular cells and its subsequent conversion to HCO_3^-. The increase in HCO_3^- helps to maintain or restore a normal pH in the general circulation. Normally, ~90% of the filtered HCO_3^- (or about 4500 mmol/day) is reclaimed in the proximal tubule, and the extent of HCO_3^- reclamation parallels Na^+ reabsorption. Thus for each H^+ secreted into the tubular fluid, one Na^+ and one HCO_3^- enter the tubular cell and return to the general circulation.

When plasma HCO_3^- concentration increases above ~28 mmol/L, the capacity of the proximal and distal tubules to reclaim is exceeded, and HCO_3^- is excreted in the urine. The process of bicarbonate reclamation is enhanced in acidosis (and decreased in alkalosis), most likely as a result of increased Na^+-H^+ exchange. In this way, the kidneys in acidosis or alkalosis support the other compensatory mechanisms to restore the normal $cHCO_3^-/cdCO_2$ ratio. Type II RTA is a decreased ability to reabsorb HCO_3^- in the proximal tubules, leading to a decrease in blood pH.

CONDITIONS ASSOCIATED WITH ABNORMAL ACID-BASE STATUS AND ABNORMAL ELECTROLYTE COMPOSITION OF THE BLOOD[6,17,25,32]

Many pathological conditions are accompanied by disturbances of the acid-base balance and electrolyte composition of the blood. These changes are usually reflected in the acid-base pattern and anion-cation composition of ECF, as measured in blood. However, results obtained on blood or plasma may not always reflect the acid-base status of the ICF.

Abnormalities of acid-base status of the blood are always accompanied by characteristic changes in electrolyte concentrations in the plasma, especially in metabolic acid-base disorders. Hydrogen ions cannot accumulate without concomitant accumulation of anions, such as Cl^- or lactate, or without exchange for cations, such as K^+ or Na^+. Consequently, electrolyte composition of blood serum or plasma is often determined along with measurements of blood gases and pH and to assess acid-base disturbances.

Acid-base disturbances are traditionally classified as (1) metabolic acidosis, (2) metabolic alkalosis, (3) respiratory acidosis, or (4) respiratory alkalosis. In simple, straight-

TABLE 46-3 Classification and Characteristics of Simple Acid-Base Disorders

	Primary Change	Compensatory Response	Expected Compensation
Metabolic			
Acidosis	$\downarrow cHCO_3^-$	$\downarrow PCO_2$	$PCO_2 = 1.5\ (cHCO_3^-) + 8 \pm 2$ PCO_2 falls by 1 to 1.3 mm Hg for each mmol/L fall in $cHCO_3^-$ Last 2 digits of pH = PCO_2 (e.g., if $PCO_2 = 28$, pH = 7.28) $cHCO_3^- + 15$ = last 2 digits of pH ($cHCO_3^- = 15$, pH = 7.30)
Alkalosis	$\uparrow cHCO_3^-$	$\uparrow PCO_2$	PCO_2 increases 6 mm Hg for each 10 mmol/L rise in $cHCO_3^-$ $cHCO_3^- + 15$ = last 2 digits of pH ($cHCO_3^- = 35$, pH = 7.50)
Respiratory			
Acidosis			
Acute	$\uparrow PCO_2$	$\uparrow cHCO_3^-$	$cHCO_3^-$ increases by 1 mmol/L for each 10 mm Hg rise in PCO_2
Chronic	$\uparrow PCO_2$	$\uparrow cHCO_3^-$	$cHCO_3^-$ increases by 3.5 mmol/L for each 10 mm Hg rise in PCO_2
Alkalosis			
Acute	$\downarrow PCO_2$	$\downarrow cHCO_3^-$	$cHCO_3^-$ falls by 2 mmol/L for each 10 mm Hg fall in PCO_2
Chronic	$\downarrow PCO_2$	$\downarrow cHCO_3^-$	$cHCO_3^-$ falls by 5 mmol/L for each 10 mm Hg fall in PCO_2

Modified from Narins RG, Gardner LB. Simple acid-base disturbances. Med Clin North Amer 1981;65:321-46.

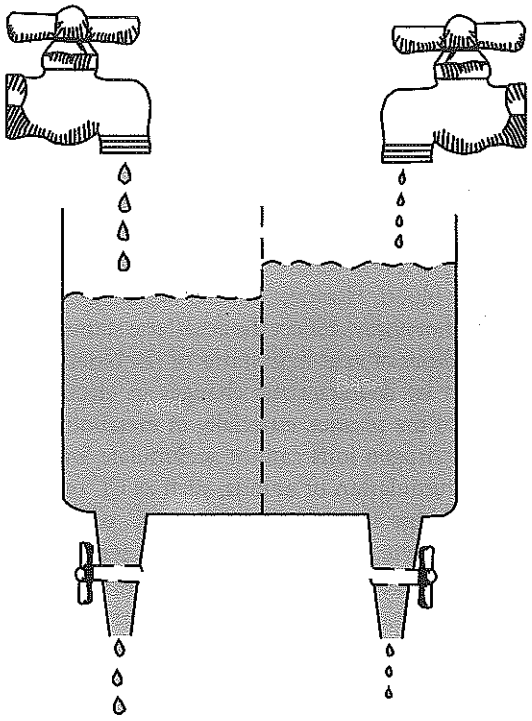

Figure 46-13 Simple depiction of the body as a two-vat system of acid and base. At equilibrium input and output from each "vat" are equal. *(From Dufour DR. Acid-base disorders. In: Dufour DR, Christenson RH, eds: Professional practice in clinical chemistry: A review. Washington DC: AACC Press, 1995:604-35.)*

forward acid-base disorders, the laboratory parameters observed for these groups are shown in Table 46-3. However, interpretation of laboratory values to classify these disorders is rarely straightforward because of compensatory responses by the respiratory and renal systems attempting to correct the imbalance.

The causes of acid-base disorders, resulting laboratory values, and compensatory responses are discussed here in the traditional categorization of these disorders. However, it is often difficult to remember which disorders fall into which categories, so it is common for mnemonic devices or tables to be used to facilitate description of these disorders. A useful and more logical approach is to realize that an acidosis can only occur as a result of one (or a combination) of three mechanisms: (1) increased addition of acid, (2) decreased elimination of acid, and (3) increased loss of base. Similarly, alkalosis occurs only by (1) increased addition of base, (2) decreased elimination of base, and (3) increased loss of acid. Dufour has illustrated this simple concept by depicting the body as a two-tank vat, one of acid and one of base, with inputs and outputs for each vat (Figure 46-13).[6] In the normal setting, these inputs and outputs are balanced; an acid-base disorder then involves a perturbation in the input or output of these body reservoirs, as discussed in the next section.

Metabolic Acidosis (Primary Bicarbonate Deficit)

Metabolic acidosis is readily detected by decreased plasma bicarbonate (or a negative extracellular base excess), the primary perturbation in this acid-base disorder. Bicarbonate is "lost" in the buffering of excess acid. Causes include the following:

1. Production of organic acids that exceeds the rate of elimination (e.g., the production of acetoacetic acid and β-hydroxybutyric acid in diabetic acidosis and of lactic acid in lactic acidosis).
2. Reduced excretion of acids (H^+) as occurs in renal failure and some RTAs, resulting in an accumulation of acid that consumes bicarbonate.
3. Excessive loss of bicarbonate because of increased renal excretion (decreased tubular reclamation) or excessive loss of duodenal fluid (as in diarrhea). Plasma $cHCO_3^-$ falls; the fall is associated with a rise in the concentration of inorganic anions (mostly chloride) or a concomitant fall in the sodium concentration.

When any of these conditions exists, the ratio of $cHCO_3^-/cCO_2$ is decreased because of the primary decrease in bicarbonate. The resulting drop in pH stimulates a respiratory compensation via hyperventilation, which lowers PCO_2 and thereby raises the pH.

Increased Anion Gap Acidosis (Organic Acidosis)

Metabolic acidoses are classified as those associated with either an increased anion gap or a normal anion gap (Table 46-4). The concept of the *anion gap* was originally devised as a quality control rule when it was noted that if the sum of Cl^- and HCO_3^- values was subtracted from the Na^+ value ($Na^+ - [Cl^- + HCO_3^-]$), the difference, or "gap," averaged 12 mmol/L in healthy subjects.[3] This *apparent* gap is due to unmeasured anions (e.g., proteins, SO_4^{2-}, $H_2PO_4^{2-}$) that are present in plasma. Anion gap values outside the interval of 7 to 16 mmol/L suggested the possibility of an error in measurement of one of the electrolytes. However, it was also apparent that the anion gap was increased in many patients with a metabolic acidosis.[7,10] Indeed, the presence of an elevated anion gap is often the first indication of a metabolic acidosis and should be assessed in the electrolyte profiles of all patients. The gap is also slightly increased in the absence of acidosis by very low calcium, magnesium, or potassium levels because lower levels of these "unmeasured" cations will result in lower levels of anions (Figure 46-14). Conversely the gap can be artificially narrowed in settings of hypoalbuminemia (negatively charged proteins), hypergammaglobulinemia (positively charged proteins), hypercalcemia, or hypermagnesemia. Taken together, these alterations have called into question its utility according to some authors.[21,33] However, the gap in these settings is usually at the extremes of the reference intervals or only slightly outside the reference intervals.

All anion gap metabolic acidoses can be explained by one (or a combination) of eight underlying mechanisms listed

TABLE 46-4 Conditions of Metabolic Acidoses with High and Normal Anion Gaps

Etiology	Retained Acids	Other Laboratory Findings
High AG*		
Methanol toxicity	Formate	↑Osmolal gap (>15 mOsmol/kg)
Uremia of renal failure	Sulfuric, phosphoric, organic	↑BUN† and serum creatinine
Ketoacidoses		
Diabetes mellitus	Acetoacetate and β-hydroxybutyrate	↑Plasma and urine glucose
Ethyl alcohol toxicity		↑Osmolal gap (>15 mOsmol/kg)
Starvation		
Paraldehyde toxicity		
Isoniazid or iron toxicity, also ischemia	Organic, mainly lactate	Isoniazid and iron act as mitochondrial poisons
Lactic acidosis	Lactate	
Ethylene glycol toxicity	Hippurate, glycolate, oxalate	↑Osmolal gap (>15 mOsmol/kg), urine oxalate crystals
Salicylate toxicity	Salicylate, organic	Respiratory alkalosis
Normal AG		
Gastrointestinal fluid loss	A primary loss of bicarbonate	
Severe diarrhea		Hypokalemia
Pancreatitis		K^+ variable
Intestinal fistula		
Renal tubular acidoses (RTA)	Sulfuric, phosphoric, organic	
Proximal (type II) RTA		Urine pH < 5.5, with K^+ normal or low
Distal (type I) RTA		Urine pH > 5.5 with hypokalemia (usually)
Type IV RTA		Urine pH < 5.5 with hyperkalemia

*Although there is considerable variability, the anion gap is often >25 mmol/L in these conditions with the exception of uremic renal failure.
†Blood urea nitrogen (reference interval: 8 to 25 mg/dL, or ~3.0 to 9.0 mmol/L).

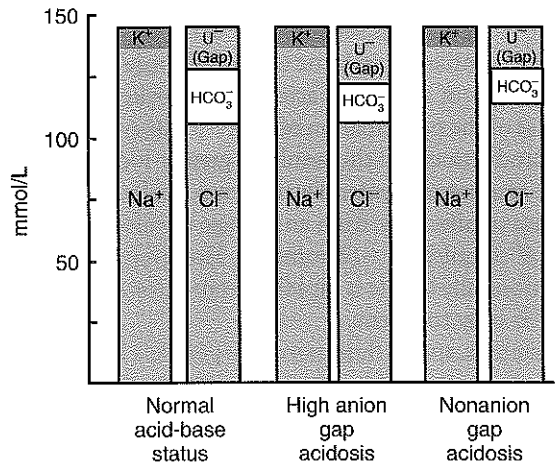

Figure 46-14 Simple "Gambelgram" depiction of normal gap, anion gap acidosis, and nonanion gap acidosis. Cations, Na^+, and K^+ are in left bar for each condition, whereas measured (Cl^- and HCO_3^-) and unmeasured (U^-) anions are in right bar for each condition.

below according to the common mnemonic device MUD-PILES (see Table 46-4). The physiological basis for the anion gap in these conditions is the consumption of bicarbonate in buffering excess acid. Cl^- values remain normal when the excess acid is any other than HCl, because the lost bicarbonate is replaced by the unmeasured anions.

Methanol

Although nontoxic itself, methanol is metabolized by the liver to formaldehyde and formic acid. Accumulation of this acid leads to metabolic acidosis with a high anion gap and to clinical symptoms of optic papillitis ("snowfield" blindness), retinal edema, and ultimately blindness because of optic nerve atrophy and neurological defects that may lead to coma. Methanol and other ingested alcohols such as ethylene glycol, ethanol, and isopropanol will increase the osmolality of plasma. Thus in the presence of a high anion gap acidosis, determination of the osmolal gap (see Chapter 27) will help determine the source of the unmeasured anion[5] and suggest specific toxicological analyses.[5]

Uremia of Renal Failure

The loss of functional renal tubular mass results in decreased ammonia formation, decreased Na^+-H^+ exchange, and

decreased GFR. All result in decreased acid excretion (see Chapter 45). Acidosis usually develops if GFR falls below 20 mL/min. Serum creatinine and blood urea nitrogen levels are usually elevated and are used as an estimate of the degree of renal damage or, more appropriately, as an estimate of remaining functional renal capacity.

Diabetes or Ketoacidosis

The pathogenesis of ketoacidosis is discussed in detail in Chapter 25. Ketoacids such as β-hydroxybutyrate and 2-oxoglutarate accumulate and represent the unmeasured anions. Accumulation of these "ketone bodies" causes a decrease in HCO_3^-, a normal or low serum chloride, and a high anion gap. Ketoacids also accumulate in states of starvation and alcoholic malnutrition.

Paraldehyde Toxicity

Paraldehyde toxicity may develop after chronic paraldehyde ingestion. The pathogenesis is poorly defined, but the acidosis may actually be a ketosis (nitroprusside negative) with β-hydroxybutyric acid as the main acidic product. Patients with paraldehyde toxicity have a pungent, apple-like odor to their breath.

Isoniazid, Iron, or Ischemia

These seemingly unrelated etiologies of high anion gap acidosis share a common feature: the accumulation of organic acids, with a predominance of lactic acid. Thus the "three I's" actually represent special cases in the general category of lactic acidosis, which is described next. Both isoniazid, an antimycobacterial agent commonly used in the treatment or prophylaxis of tuberculosis, and iron toxicity involve the production of toxic peroxides that act as mitochondrial poisons and interfere with normal cellular respiration. In addition, isoniazid may be hepatotoxic, leading to significant liver damage and impairment of lactate clearance.[16]

Tissue ischemia may result from many causes; in general, hypoperfusion leads to hypoxia of cells, which results in anaerobic metabolism with the attendant accumulation of organic (mainly lactic) acids. The kidneys (and brain) are especially sensitive to hypoperfusion, such that acute renal failure often is a contributing factor in the high anion gap metabolic acidosis associated with global tissue ischemia (as may occur in major trauma).

Lactic Acidosis

Lactic acid, present in blood entirely as lactate ion ($pK = 3.86$), is an intermediate of carbohydrate metabolism and is derived mainly from muscle cells and erythrocytes (see Chapter 25). It represents the end product of anaerobic metabolism and is normally metabolized by the liver. The blood lactate concentration is, therefore, affected by the rate of production and the rate of metabolism, both of which are dependent on adequate tissue perfusion. An increase in the concentration of lactate to >2 mmol/L and the associated increased H^+ is considered lactic acidosis.

Lactic acidosis caused by severe tissue hypoxia is seen in severe anemia, shock, cardiac decompensation, and pulmonary insufficiency. Severe oxygen deprivation of tissue blocks aerobic oxidation of pyruvic acid in the tricarboxylic acid cycle and results in the reduction of pyruvate to form lactate. Lactic acidosis is associated with a significant increase in the lactate/pyruvate ratio in blood. Such extreme findings signal deterioration of the cellular oxidative process and are associated with marked tachypnea, weakness, fatigue, stupor, and finally coma. Conditions at these later stages are frequently irreversible, even when treatment for acidosis and hypoxia is instituted. Examples are the irreversible, end-stage of shock; diabetic coma without ketosis; and a variety of illnesses in the terminal stage. A short-lived lactic acidosis is often observed following grand mal seizures. If the origin of lactate (e.g., seizure and hypoxic tissue) can be rectified, lactate is rapidly metabolized to CO_2, which is then eliminated if the respiratory system is intact.

Lactic acidosis is also caused by (1) drugs and toxins, such as ethanol, methanol, biguanides, isoniazid (see previous discussion), and streptozotocin; (2) acquired and hereditary defects in enzymes involved in gluconeogenesis; (3) disorders such as severe acidosis, uremia, liver failure, tumors, and seizures; (4) anesthesia; and (5) abnormal intestinal bacteria producing D-lactate (described in Chapter 25).

Alcohol taken in excess tends to prevent gluconeogenesis from lactate in the liver, because oxidation of ethanol to acetaldehyde competes for the NAD^+ that is necessary for the conversion of lactate to pyruvate. Severe acidosis, such as diabetic ketoacidosis, may suppress lactate conversion and cause a shift in the lactate-pyruvate equilibrium with the accumulation of H^+. This shift may, in part, be responsible for the lactic acidosis seen in diabetics.

Hyperventilation in lactic acidosis is more intense than in other forms of metabolic acidosis. It is believed that this is because of the participation of the respiratory center in lactic acid production and the resulting greater local acidification of the respiratory center. During exercise, lactate levels may increase significantly, from an average normal concentration of ~0.9 mmol/L to ~12 mmol/L. However, under normal conditions, the lactate is rapidly metabolized so that the "acidosis" is only transient.

Lactate in spinal fluid normally parallels blood levels. In cases of biochemical alterations in the central nervous system, however, CSF lactate values change independently of blood values. Increased CSF levels may be seen in intracranial hemorrhage, bacterial meningitis, epilepsy, and other CNS disorders.[31]

Ethylene Glycol

Ingested ethylene glycol is metabolized to glycolic and oxalic acids and other acidic metabolites. Its metabolism leads to an acidosis with high anion and osmolal gaps. Accumulation of toxic metabolites may contribute to lactic acid production that further contributes to the acidosis. Precipitation of calcium oxalate and hippurate crystals in the urinary tract

may lead to acute renal failure. Clinically, patients develop a variety of neurological symptoms that may lead to coma. Some patients may develop, either singly or in combination, (1) bronchial pneumonia, (2) pulmonary edema, (3) congestive heart failure, (4) hypertension, or (5) cardiopulmonary arrest. The minimal lethal dose of ethylene glycol is ~100 mL for an average 70 kg adult.

Salicylate Intoxication

This generally occurs with blood salicylate concentrations above 30 mg/dL. Salicylate, itself an unmeasured anion, alters peripheral metabolism, leading to the production of various organic acids without dominance of any specific acid. The processes eventually result in a metabolic acidosis with a high anion gap. Salicylate also stimulates the respiratory center to increase the rate and depth of respiration, resulting in a low PCO_2, low HCO_3^-, and respiratory alkalosis (see the section entitled Respiratory Alkalosis). In adults, mixed respiratory alkalosis and metabolic acidosis are more common, whereas in children, metabolic acidosis predominates.

Normal Anion Gap Acidosis (Inorganic Acidosis)

In contrast to high anion gap acidoses, in which bicarbonate is consumed in buffering excess H^+, the cause of acidosis in the presence of a normal anion gap is the loss of bicarbonate-rich fluid from either the kidney or gastrointestinal tract. As bicarbonate is lost, more Cl^- ions are reabsorbed with Na^+ or K^+ to maintain electrical neutrality so that hyperchloremia ensues (see Figure 46-14). Normal anion gap acidosis can be divided into *hypokalemic* and *normokalemic* acidoses, which can be helpful in the differential diagnosis of this type of disorder (see Table 46-4).

Diarrhea

Diarrhea may cause acidosis as a result of loss of Na^+, K^+, and HCO_3^-. One of the primary exocrine functions of the pancreas is production of HCO_3^- to neutralize gastric contents on entry into the duodenum. If the water, K^+, and HCO_3^- in the intestine are not reabsorbed, a hypokalemic, normal anion gap metabolic acidosis will develop. The resulting hyperchloremia is due to the replacement of lost bicarbonate with Cl^- to maintain electrical balance.

Renal Tubular Acidoses, Types I and II

These syndromes are predominantly characterized by loss of bicarbonate because of decreased tubular secretion of H^+ (distal or type I RTA) or decreased reabsorption of HCO_3^- (proximal or type II RTA).[15] Because the major urine-acidifying power of the kidneys rests in the distal tubules, the proximal and distal RTAs may be differentiated by measurement of urine pH. In proximal RTA, urine pH becomes <5.5, whereas in distal RTA the distal tubules are compromised and urine pH is >5.5.[15] When distal RTA is associated with obstructive nephropathy, sickle cell disease, or systemic lupus erythematosus, hyperkalemia may be seen. Otherwise, distal RTA is usually accompanied by hypokalemia.

Carbonic Anhydrase Inhibitors

Acetazolamide is the most common drug in this class of therapeutic agents. It is infrequently used as a mild diuretic. More often, it is used for urine alkalinization and in patients suffering from open-angle glaucoma or acute mountain (altitude) sickness.[12] Inhibition of carbonic anhydrase causes wasting of Na^+, K^+, and HCO_3^- in the proximal tubules and represents a pharmacologically induced proximal RTA.

Hyperkalemic Normal Anion Gap Acidosis (Renal Tubular Acidosis Type IV)

Failure of the kidneys to synthesize renin, failure of the adrenal cortex to secrete aldosterone, and renal tubular resistance to aldosterone are the most common causes of this type of acidosis (often called type IV RTA). This inhibits Na^+ reabsorption, and both K^+ and H^+ are thus abnormally retained. The result is decreased renal ammonia formation and therefore decreased elimination of H^+. If associated with increased ECF volume, HCO_3^- reclamation in the tubules may be depressed. There is usually an associated mild renal insufficiency (elevated serum creatinine), but urine may still be acidified to a pH < 5.5. Hyperkalemia is also usually present.

Compensatory Mechanisms in Metabolic Acidosis

The buffer systems of the blood (mainly the bicarbonate/carbonic acid buffer) minimize changes in pH. In acidoses, the bicarbonate concentration decreases to give a ratio of $cHCO_3^-/cdCO_2$ of <20:1. The respiratory compensatory mechanism responds to correct the ratio with increased rate and depth of respiration to eliminate CO_2. Table 46-3 depicts expected compensation in both acidoses and alkaloses and corresponding laboratory values.

Respiratory Compensatory Mechanism

The decrease in pH in metabolic acidosis stimulates the respiratory compensatory mechanism and produces hyperventilation (Kussmaul respiration), which results in the elimination of carbonic acid as CO_2, a decrease in PCO_2 (hypocapnia), and consequently a decrease in $cdCO_2$. There is also a decrease in $cHCO_3^-$ that is smaller than that of $cdCO_2$. For example, the ratio of $cHCO_3^-/cdCO_2$ might be 16:1.28 (12:5:1) for a pH of 7.2 before compensation and 14.5:0.9 (16:1:1) for a pH of 7.30 after compensation (see Figure 46-8). As the $cdCO_2$ diminishes, the ratio of $cHCO_3^-/cdCO_2$ approaches its normal value of 20:1.

Renal Compensatory Mechanism

If possible, the kidneys respond to restore the normal pH by increased excretion of acid and preservation of base (increased rate of Na^+-H^+ exchange, increased ammonia formation, and increased reabsorption of bicarbonate). When the renal compensating mechanisms are functioning, urinary acidity and urinary ammonia are increased. The total amount of H^+ excreted may be as much as

500 mmol/day. As a result, $c\mathrm{HCO_3^-}/c\mathrm{dCO_2}$ will increase, for example, to 22:1.1 (20:1) for a pH of 7.40. *This is a fully compensated metabolic acidosis,* because the pH has returned to normal; however, acidosis still exists because a process that consumes $\mathrm{HCO_3^-}$ persists. Physiologically a normal pH suggests that the acidosis is overcompensated.

Laboratory Findings in Metabolic Acidosis

Bicarbonate concentrations have been used to empirically estimate pH and $P\mathrm{CO_2}$. For pH, 15 is added to the determined bicarbonate concentration for an estimate of the decimal digits of pH. For example, a patient who has been acidotic for at least 12 to 24 hours and has a bicarbonate of 10 mmol/L (10 + 15 = 25) will have an estimated pH of 7.25. For estimating $P\mathrm{CO_2}$ (mm Hg), the following formula is sometimes used:[1]

$$P\mathrm{CO_2} \pm 2 = 1.5(c\mathrm{HCO_3^-}) + 8$$

For this example, the $P\mathrm{CO_2}$ estimate would be 1.5(10) + 8, or 23 ± 2 (see Table 46-3). Use of this equation can have important clinical implications, because it indicates whether a given $P\mathrm{CO_2}$ value is appropriate for a given degree of metabolic acidosis or if one is dealing with a mixed acid-base disorder. Another common estimator of proper compensation is that the $P\mathrm{CO_2}$ will equal the last two digits of the pH. If a respiratory acidosis is superimposed on a preexisting metabolic acidosis, the $P\mathrm{CO_2}$ would be higher than expected by either of these estimates.

Electrolytes are also altered depending on the cause of metabolic acidosis. In diabetic ketoacidosis, the increase in the fraction of organic acids caused by increased ketone body production is reflected by a decrease in plasma bicarbonate and sometimes in chloride. Plasma Na^+ and K^+ are also decreased because of the associated polyuria and coexcretion of these cations with acetoacetate and β-hydroxybutyrate. Furthermore, because of the high glucose, there is a dilutional effect as a result of the osmotically induced increase in vascular volume. When glucose concentration decreases following insulin treatment, water leaves the vascular compartment, and Na^+ concentration increases. Serum potassium levels, however, may be normal or even high, despite severe total body depletion of K^+; the serum level represents a balance struck between the amount of K^+ lost in the urine, the amount of K^+ shifted from cells into ECF, and the degree of dehydration.

In renal failure, organic acids, phosphate, and sulfate are increased because of retention. Chronic metabolic acidosis enhances mobilization of calcium from bone; the decrease in plasma pH increases dissociation of plasma protein-bound calcium so that more Ca^{2+} is filtered through the glomerulus and less is reabsorbed in the tubule (see also Chapter 45).

Metabolic Alkalosis (Primary Bicarbonate Excess)

Alkalosis occurs either when excess base is added to the system, base elimination is decreased, or acid-rich fluids are lost (Box 46-1). Any of these can lead to a primary bicarbonate excess, such that the ratio of $c\mathrm{HCO_3^-}/c\mathrm{dCO_2}$ becomes >20:1. For instance, a primary increase in bicarbonate to 48 mmol/L will alter the $c\mathrm{HCO_3^-}/c\mathrm{dCO_2}$ to 48:1.5 (32:1) for a pH of 7.6 (see Figure 46-8). The patient will hypoventilate to raise $P\mathrm{CO_2}$ and therefore lower the pH toward normal. However, hypoxia usually prevents the patient from achieving a $P\mathrm{CO_2}$ >55 mm Hg.

If the increase in pH is great enough, increased neuromuscular activity may be seen, and above pH 7.55, tetany may develop even in the presence of a normal serum total calcium concentration. The cause of the tetany is a decreased concentration of ionized calcium due to increased binding of calcium ions by protein (mainly albumin) and other anions. Measurement of Cl^- status can be helpful, as causes of metabolic alkalosis fall into Cl^- responsive, Cl^- resistant, and exogenous base categories (Box 46-1; see also Figure 46-4).

BOX 46-1 Conditions Leading to Metabolic Alkalosis

Chloride-Responsive (Urine Cl^- < 10 mmol/L)
Contraction alkaloses
- Prolonged vomiting or nasogastric suction
- Pyloric or upper duodenal obstruction
- Prolonged or abusive diuretic therapy (loop diuretics)
- Villous adenoma

Posthypercapnic state
Cystic fibrosis (systemic ineffective reabsorption of Cl^-)

Chloride-Resistant (Urine Cl^- > 20 mmol/L)
Mineralocorticoid excess
- Primary hyperaldosteronism (adrenal adenoma or rarely, carcinoma)
- Bilateral adrenal hyperplasia
- Secondary hyperaldosteronism
- Hyperreninemic hyperaldosteronism (hypertension)
- Congenital adrenal hyperplasia (due to adrenal enzyme deficiencies in cortisol production [11β- or 17α-hydroxylase])

Glucocorticoid excess
- Primary adrenal adenoma (Cushing's syndrome)
- Pituitary adenoma secreting ACTH (Cushing's disease)
- Exogenous cortisol therapy
- Excessive licorice ingestion

Bartter's syndrome (defective renal Cl^- reabsorption)

Exogenous Base
Iatrogenic
- Bicarbonate-containing intravenous fluid therapy
- Massive blood transfusion (sodium citrate overload)
- Antacids and cation-exchange resins in dialysis patients
- High-dose carbenicillin or penicillin (associated with hypokalemia)

Milk-alkali syndrome

Cl^- Responsive Metabolic Alkalosis

Most causes of Cl^- responsive metabolic alkalosis occur as a result of *hypovolemia* (see Box 46-1). When the ECF is severely depleted, the resulting acid-base disorder is often referred to as "contraction alkalosis." Renal bicarbonate retention will occur in response to hypovolemia under the action of increased aldosterone. This also will result in increased reabsorption of Na^+ together with HCO_3^- and excretion of K^+ and H^+. The resulting hypokalemia contributes to the alkalosis, as described previously. Urine Cl^- will be <10 mmol/L as both the available Cl^- and HCO_3^- are reabsorbed with Na^+. Urine Na^+ is not useful for classifying metabolic alkalosis because there will be an obligatory loss of Na^+ when filtered HCO_3^- exceeds reclamation. Common causes of contraction alkalosis include prolonged vomiting or nasogastric suction, pyloric or upper duodenal obstruction, villous adenoma (unregulated secretion of HCl), and the use of certain diuretics. Treatment consists of replacing TBW with water and NaCl tablets or saline infusion.

Gastrointestinal Loss of HCl

Following prolonged vomiting, pyloric or high intestinal obstruction, or gastric suction, excessive loss of hydrochloric acid from the stomach and *hypovolemia* may occur. In this hypochloremic, hypovolemic setting the kidneys preferentially reabsorb Na^+ to restore volume and excess bicarbonate is reabsorbed in the absence of sufficient Cl^- to maintain electrical neutrality. In addition, H^+ and K^+ are secreted in exchange for Na^+. Urine Cl^- will be <10 mmol/L in this setting (see Figure 46-4).

Diuretic Therapy

Prolonged administration of certain diuretics has been known to cause an alkalosis that is similar to that observed in a hypovolemic setting. Most common are those acting on the ascending limb of the loop of Henle (e.g., furosemide [Lasix], bumetanide [Bumex]) that block sodium, potassium, and chloride reabsorption. The resulting increase in Na^+ concentration reaching the distal convoluted tubule, particularly when combined with activation of the renin-angiotensin-aldosterone axis, leads to increased urinary excretion of K^+ and H^+.[12] The loss of K^+ with furosemide is much greater than with thiazides. Continued abuse or unmonitored use of loop diuretics can lead to volume contraction and a contraction alkalosis. This is commonly seen among patients abusing diuretics for the purpose of weight loss.

Cl^- Resistant Metabolic Alkalosis

This condition is far less common than chloride responsive metabolic alkalosis and is almost always associated with either an underlying disease (primary hyperaldosteronism, Cushing's syndrome, or Bartter's syndrome) or with excess addition of exogenous base. In these conditions, urine Cl^- will usually be >20 mmol/L.

In states of adrenocortical excess (endogenous or pharmacological, primary or secondary) K^+ and H^+ are "wasted" by the kidneys as a consequence of the increased Na^+ reabsorption stimulated by elevated aldosterone or cortisol. The attendant hypokalemia often further contributes to the alkalosis and should be treated with replacement therapy. The resulting decreased tubular K^+ concentration stimulates NH_3 production and thus renal H^+ excretion as NH_4^+. This is accompanied by enhanced HCO_3^- reabsorption (see Figures 46-3 and 46-12). Diseases in which endogenous mineralocorticoids, glucocorticoids, or both are elevated include primary and secondary hyperaldosteronism, bilateral adrenal hyperplasia, pituitary ACTH-producing adenoma (Cushing's disease), and primary adrenal adenomas producing glucocorticoids (Cushing's syndrome) or aldosterone.

Excessive licorice ingestion may cause a form of chloride resistant alkalosis. Black licorice contains glycyrrhizic acid, which inhibits the enzyme 11-β hydroxysteroid dehydrogenase, which in turn catalyzes the conversion of cortisol to cortisone. The excess cortisol exerts a mineralocorticoid effect on the distal tubule aldosterone receptors.[8]

Finally a rare etiology of Cl^- resistant metabolic alkalosis is a genetic (autosomal recessive) defect in Cl^- reabsorption within the thick ascending limb of the loop of Henle, a condition known as Bartter's syndrome.[4]

Exogenous Base

Examples in this category include citrate toxicity following massive blood transfusion, aggressive intravenous therapy with bicarbonate solutions, and ingestion of large quantities of milk and antacids in the treatment of gastritis and peptic ulcers ("milk-alkali syndrome"). The latter is far less commonly seen since the introduction and now widespread use of H_2-receptor antagonists and proton-pump inhibitors. Finally the use of antacids and cationic exchange resins in patients with renal failure (especially those on dialysis) may result in a metabolic alkalosis.

Compensatory Mechanisms in Metabolic Alkalosis

The compensatory mechanisms for metabolic alkalosis include both respiratory compensation and, if physiologically possible, renal compensation.

Respiratory Compensatory Mechanism

The increase in pH depresses the respiratory center, causing a retention of carbon dioxide (hypercapnia), which in turn causes an increase in cH_2CO_3 and $cdCO_2$. Thus the ratio of $cHCO_3^-/cdCO_2$, which was originally increased, approaches its normal value, although the actual concentrations of both $cHCO_3^-$ and $cdCO_2$ remain increased. The respiratory response to metabolic alkalosis is erratic, and increases in PCO_2 are variable.

Renal Compensatory Mechanism

The kidneys respond to the state of alkalosis by decreased Na^+-H^+ exchange, decreased formation of ammonia, and decreased reclamation of bicarbonate. This response is blunted, however, in conditions of hypokalemia and hypovolemia.

Laboratory Findings in Metabolic Alkalosis

Blood plasma values for $cHCO_3^-$, $cdCO_2$, and PCO_2, and therefore the plasma total CO_2 concentration, are increased, and the ratio of $cHCO_3^-/cdCO_2$ is high. In uncomplicated metabolic alkalosis, the PCO_2 increases by ~6 mm Hg for each 10 mmol/L rise in $cHCO_3^-$. A higher than expected PCO_2 may indicate superimposed respiratory acidosis. The extent of increase of pH in uncompensated metabolic alkalosis can be estimated by adding 15 to the $cHCO_3^-$ to give the last two digits of the pH. If the $cHCO_3^-$ is 35 mmol/L, the estimated pH would be 7.50 (35 + 15 = 50). In cases of prolonged vomiting, Cl^- (and sometimes K^+) concentrations are low because of the loss of these ions through the vomitus. Protein values may be falsely increased owing to dehydration, and if food intake is inadequate, formation of ketone bodies may increase the organic acid fraction. In cases of excessive administration of $NaHCO_3$, Na^+ levels are increased.

In patients with adequate renal function, urinary pH values are usually increased because of the decreased excretion of acid and increased excretion of bicarbonate. Urinary ammonia values are decreased because of decreased formation of ammonia in the tubules. In K^+ depletion, H^+ is preferentially exchanged for Na^+ and the pH of the urine may be low. This is called *paradoxical aciduria.*

Respiratory Acidosis

Any condition that decreases elimination of carbon dioxide through the lungs results in an increase in PCO_2 (hypercapnia) and a primary excess of dCO_2 (respiratory acidosis). Thus respiratory acidosis only occurs by decreased elimination of CO_2. Causes of decreased CO_2 elimination (Box 46-2) are classified as acute or chronic. Alternatively, these conditions may be separated into those caused by factors that directly depress the respiratory center (such as centrally acting drugs, CNS trauma, and infections) and those that affect the respiratory apparatus or cause mechanical obstruction of the airways. Chronic obstructive pulmonary disease is the most common cause. Rebreathing, or breathing air high in CO_2 content, may also cause a high PCO_2. Increase in PCO_2 results in an increase of $cdCO_2$ (and thus H_2CO_3, which dissociates to H^+ and HCO_3^-), which in turn causes a decrease in the $cHCO_3^-/cdCO_2$ ratio (e.g., the ratio may be 28:1.7 (16:1) for a pH of ~7.30; see Figure 46-8). A doubling of PCO_2 will cause a fall in pH of about 0.23 when other factors remain constant.

Compensatory Mechanisms in Respiratory Acidosis

Compensation for respiratory acidosis occurs immediately via buffers and with time via the kidneys and, if possible, the lungs.

Buffer System

Excess carbonic acid present in blood is to a great extent buffered by the hemoglobin and protein buffer systems[9] (see Figure 46-9). The buffering of CO_2 causes a slight rise in $cHCO_3^-$. Thus in the immediate posthypercapnic state, this compensation may appear as a metabolic alkalosis (see Box 46-1).

BOX 46-2 Conditions Leading to Respiratory Acidosis

Factors That Directly Depress the Respiratory Center
Drugs such as narcotics and barbiturates
Central nervous system (CNS) trauma, tumors, and degenerative disorders
Infections of the CNS such as encephalitis and meningitis
Comatose states such as cerebrovascular accident due to intracranial hemorrhage
Primary central hypoventilation

Conditions That Affect the Respiratory Apparatus
Chronic obstructive pulmonary disease (most common cause)
Pulmonary fibrosis
Status asthmaticus (severe)
Diseases of the upper airways such as laryngospasm or tumor
Pulmonary infections (severe)
Impaired lung motion due to pleural effusion or pneumothorax
Adult respiratory distress syndrome
Chest wall diseases and chest wall deformities
Neurological disorders affecting the muscles of respiration

Others
Abdominal distention, as in peritonitis and ascites
Extreme obesity (pickwickian syndrome)
Sleep disorders such as sleep apnea

Renal Mechanism

The kidneys respond to respiratory acidosis similar to the way that they do to metabolic acidosis; namely, with (1) increased Na^+-H^+ exchange, (2) increased ammonia formation, and (3) increased reclamation of bicarbonate. In a partially compensated chronic respiratory acidosis at steady state, the plasma pH is returned about halfway toward normal as compared with the acute (uncompensated) situation. Renal compensation is not effective before 6 to 12 hours and is not optimal until 2 to 3 days. In chronic respiratory acidosis, such as occurs in patients with chronic obstructive pulmonary disease (COPD), full renal compensation may be seen even in those patients with very high PCO_2 (>50 mm Hg). However, these severe COPD patients often present with a superimposed metabolic alkalosis arising from a variety of causes, such as prolonged administration of diuretics.

Respiratory Mechanism

The increase in PCO_2 stimulates the respiratory center and results in increased pulmonary rate and depth of respiration provided that the primary defect is not in the respiratory center. The elimination of carbon dioxide through the lungs results in a decrease in $cdCO_2$, and thus the ratio of $cHCO_3^-/cdCO_2$ and pH approaches normal.

BOX 46-3 Factors Causing Respiratory Alkalosis

Nonpulmonary Stimulation of Respiratory Center
Anxiety, hysteria
Febrile states
Gram-negative septicemia
Metabolic encephalopathy (e.g., due to liver disease)
Central nervous system infections such as meningitis, encephalitis
Cerebrovascular accidents
Intracranial surgery
Hypoxia (e.g., severe anemia, high altitudes [acute condition])
Drugs and agents such as salicylates, catecholamines, and progesterone
Pregnancy, mainly third trimester (↑ progesterone?)
Hyperthyroidism

Pulmonary Disorders*
Pneumonia
Asthma
Pulmonary emboli
Interstitial lung disease
Large right to left shunt ($PCO_2 < 50$ mm Hg)
Congestive heart failure
Respiratory compensation after correction of metabolic acidosis

Others
Ventilator-induced hyperventilation

*The severe stages of some of these disorders may be associated with respiratory acidosis if elimination of CO_2 is severely impaired.

Laboratory Findings in Respiratory Acidosis

Plasma $cdCO_2$, PCO_2, $cHCO_3^-$, and therefore $ctCO_2$ are elevated in respiratory acidoses. Because of an increase in $cdCO_2$, the ratio of $cHCO_3^-/cdCO_2$ is decreased, resulting in a decreased pH. In the acute phase, $cHCO_3^-$ will increase about 1 mmol/L for each 10 mm Hg rise in PCO_2. If respiratory acidosis persists, the change will be 3.5 mmol/L, mainly as a result of renal compensation. For every 15 mm Hg increase in PCO_2, the pH changes in the *acute* phase by ~0.10 pH unit and in *chronic* conditions by slightly less than 0.05 pH unit. For example, if the PCO_2 increases acutely by 30 mm Hg, the pH drops to ~7.20. The same PCO_2 increase in a chronic condition results in a pH of ~7.31. The plasma chloride decreases as plasma bicarbonate increases. Hyperkalemia may occur but is not as predictable as in some forms of metabolic acidosis. For every 0.1 unit decrease in pH, there is generally an inverse change of 0.6 mmol/L in K^+. This increase in K^+ is mainly due to the movement of K^+ from cells into the plasma in exchange for the movement of H^+ into cells. Urinary acidity and ammonia content are increased as the kidney attempts to compensate.

Respiratory Alkalosis

A decrease in PCO_2 (hypocapnia) and the resulting primary deficit in $cdCO_2$ (respiratory alkalosis) are caused by an increased rate or depth of respiration, or both. Therefore, the basic cause of respiratory alkalosis is excess elimination of acid via the respiratory route. Excessive elimination of carbon dioxide reduces the PCO_2 and causes an increase in the $cHCO_3^-/cdCO_2$ ratio (due to decrease in $cdCO_2$). The latter shifts the normal equilibrium of the bicarbonate/carbonic acid buffer system, reducing the hydrogen ion concentration and increasing the pH. This shift also results in a decrease in $cHCO_3^-$, which somewhat ameliorates the change in pH. Analogous to causes of respiratory acidosis, causes of respiratory alkalosis can be classified as those with a direct stimulatory effect on the respiratory center and those due to effects on the pulmonary system. These and some additional conditions underlying respiratory alkaloses are listed in Box 46-3.

Compensatory Mechanisms in Respiratory Alkalosis

The compensatory mechanisms respond to respiratory alkalosis in two stages. In the first stage, erythrocyte and tissue buffers provide H^+ ions that consume a small amount of HCO_3^-. The second stage becomes operational in prolonged respiratory alkalosis and depends on the renal compensation as described for metabolic alkalosis (decreased reclamation of bicarbonate).

Laboratory Findings in Respiratory Alkalosis

In this condition, the $cdCO_2$, PCO_2, $cHCO_3^-$, and thus the total CO_2 concentration all decrease. The ratio of $cHCO_3^-/cdCO_2$ is increased and causes an increase in pH.

During the acute phase, $cHCO_3^-$ falls by 2 mmol/L for each 10 mm Hg decrease in PCO_2 (i.e., if the PCO_2 falls by 20 mm Hg, $cHCO_3^-$ decreases by 4 mmol/L). For the same 20 mm Hg decrease in PCO_2, the $[H^+]$ will decrease by 16 nmol/L.

$$\Delta cH^+ = 0.8(\Delta PCO_2)$$
$$\Delta cH^+ = 0.8 \times 20 = 16$$

If the original cH^+ was 40 nmol/L, it would now be 24 nmol/L (40 − 16 = 24), which corresponds to a pH of 7.61 (see Figure 46-6). In chronic respiratory alkalosis, the $cHCO_3^-$ falls only ~5 mmol/L for every 10 mm Hg decrease in PCO_2 and the pH will return to near normal. Finally, individuals living at high altitudes chronically hyperventilate owing to hypoxia and have PCO_2 values lower than those seen at sea level.

CHAPTER 47

Liver Disease*

D. Robert Dufour, M.D.

The liver has a central and critical biochemical role in the metabolism, digestion, detoxification, and elimination of substances from the body. All blood from the intestinal tract initially passes through the liver, where products derived from digestion of food are processed, transformed, and stored. These include amino acids, carbohydrates, fatty acids, cholesterol, lipids, vitamins, and minerals. Most major plasma proteins (with the exception of immunoglobulins and von Willebrand factor) are either mainly or exclusively synthesized in the liver. The liver responds to multiple hormonal and neural stimuli to regulate the blood glucose concentration. Not only does it extract glucose from blood for use in generating energy, it also stores dietary glucose as glycogen for later use. The liver is also the major site for gluconeogenesis, critical for maintaining blood glucose in the fasting state. The liver is critical in lipid metabolism; not only does it extract and process dietary lipids, it is the principal site of cholesterol, triglyceride, and lipoprotein synthesis. Another major liver function is the synthesis of bile acids from cholesterol and secretion of these compounds into the bile, facilitating the absorption of dietary fat and fat soluble vitamins. The liver is also the main site of metabolism of both endogenous substances and exogenous compounds, such as drugs and toxins. This process, known as biotransformation, converts lipophilic substances to hydrophilic ones for subsequent elimination. The liver is a major site of catabolism of thyroid, steroid, and other hormones, and thus participates in regulation of plasma hormone concentrations. The liver is also involved in hormone synthesis, producing such hormones as insulin-like growth factor 1, angiotensinogen, and erythropoietin. Many of these hepatic functions may be assessed by laboratory procedures to gain insight into the integrity of the liver.

As a large organ, the liver shares with many other organs the ability to perform its functions with extensive reserve capacity. In many cases, individuals with liver disease maintain normal function despite extensive liver damage. In such cases, liver disease may only be recognized by using tests that detect injury. Most commonly, this is accomplished by measurement of plasma activities of enzymes found within liver cells released in somewhat specific patterns with different forms of injury. Chronic liver injury often involves fibrosis in the liver; detection of markers of the fibrotic process might be indicators of degree of injury. Chronic damage is often due to chronic inflammation; cytokines alter the pattern of liver protein production, allowing detection of inflammation (although not necessarily that involving the liver). Some proteins are produced in increased amounts with liver regeneration and neoplasm; such markers may be useful in detecting liver cell proliferation.

The chapter begins with a discussion of the anatomy and biochemical functions of the liver. The various disease states that involve the liver are then discussed. The chapter concludes with a discussion of use of laboratory test results in recognizing and characterizing patterns of liver injury.

ANATOMY OF THE LIVER

The liver weighs approximately 1.2 to 1.5 kg in the adult. It is located beneath the diaphragm in the right upper quadrant of the abdomen and is protected by the ribs and held in place by ligamentous attachments.

Gross Anatomy

The liver is divided into left and right anatomical lobes by the falciform ligament, an anterior extension of the peritoneal folds that connects the liver to the diaphragm and anterior abdominal wall (Figure 47-1). Two smaller lobes are found on the posterior surface (caudate lobe) and the infe-

*The author gratefully acknowledges the original contributions by Drs. Keith G. Tolman and Robert Rej upon which portions of this chapter are based.

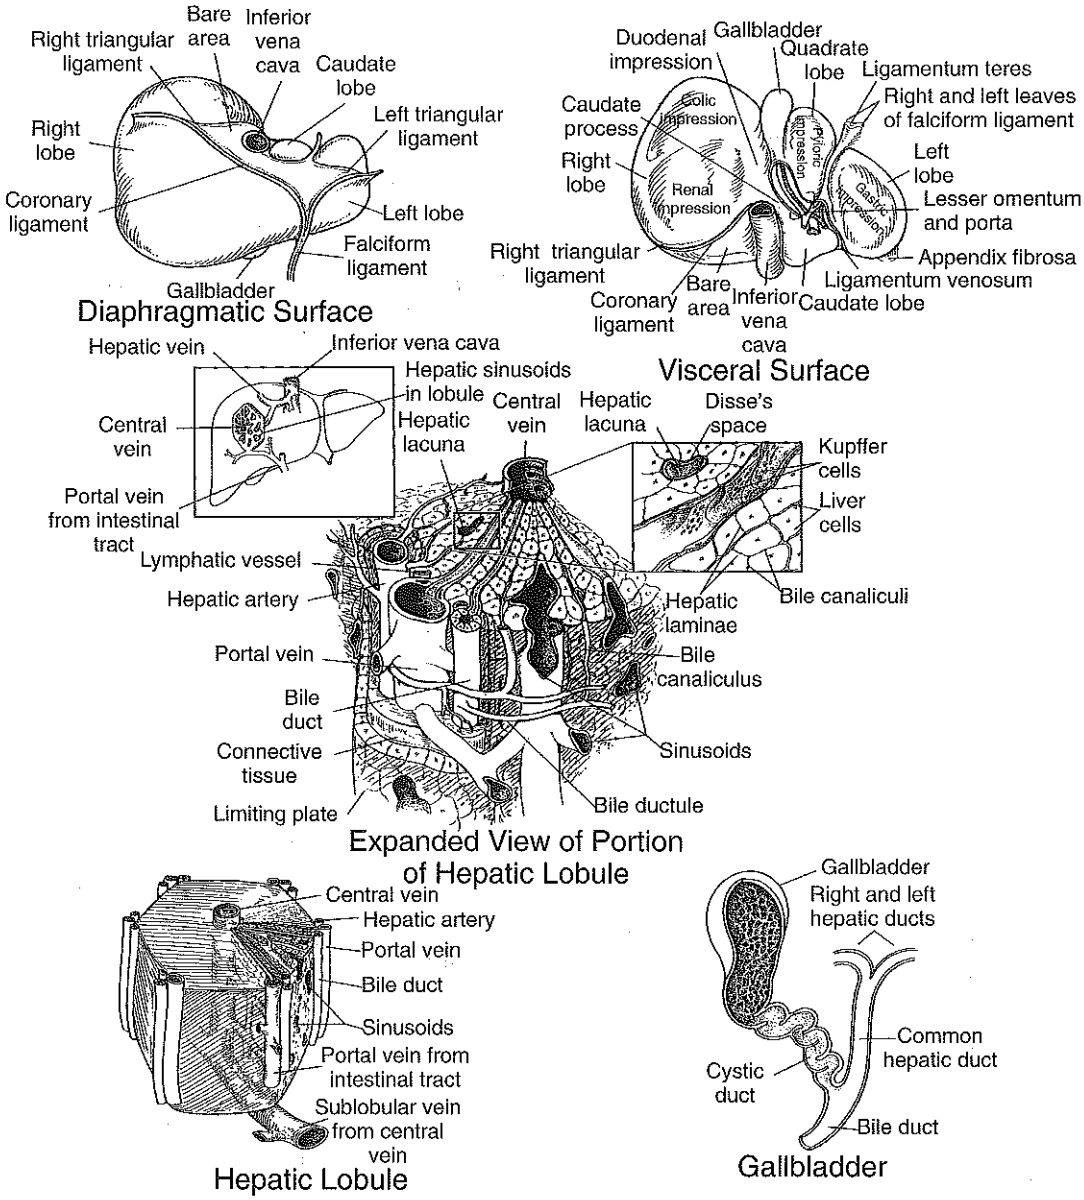

Figure 47-1 Structure of the liver. *(From Dorland's illustrated medical dictionary, 30th ed. Philadelphia: WB Saunders, 2003, plate 26.)*

rior surface (quadrate lobe) of the right lobe. Riedel's lobe is an anatomical extension of the right lobe of the liver and consists of a projection that may feel like a mobile tumor in the right abdomen.

The liver has a dual blood supply. The portal vein, which carries blood from the spleen and nutrient-enriched blood from the gastrointestinal (GI) tract, supplies approximately 70% of the blood supply, while the hepatic artery, a branch of the celiac axis, provides oxygen-enriched arterial blood. Each supplies approximately half of the oxygen reaching the liver, making it highly resistant to infarction. Ultimately, these two blood supplies merge and flow into the sinusoids that course between individual hepatocytes. The venous drainage from the liver ultimately converges into the right and left hepatic veins, which exit on the posterior surface of the liver and join the inferior vena cava near its entry into the right atrium.

The liver is covered with an anterior reflection of the peritoneum known as Glisson's capsule. Other extensions of the peritoneum form ligaments that hold the liver in place. Internal extensions of the capsule provide an internal supporting framework that divides the liver into lobules and ultimately surrounds blood vessels and nerves. One of the ligaments, the ligamentum teres, is the vestigial remnant of the umbilical vein and connects the umbilicus to the inferior border of the liver. When portal hypertension occurs, the umbilical veins may reopen, leading to venous dilation around the umbilicus (termed caput medusae).

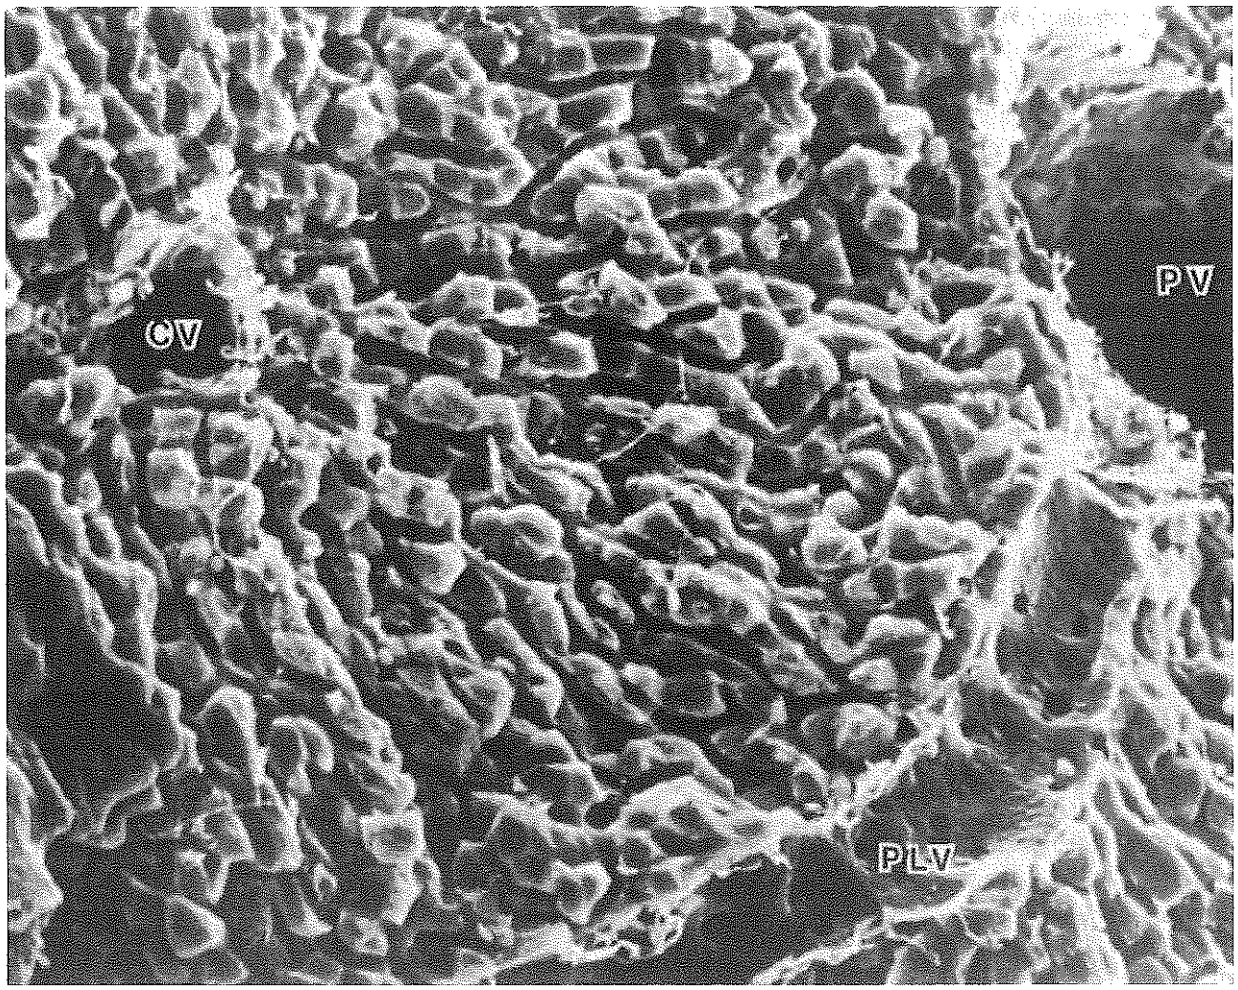

Figure 47-2 A low-magnification scanning electron micrograph depicting a portion of a liver lobule from a rat liver. *CV,* Central vein; *PV,* portal vein; *PLV,* perilobular venules. *(From Zakim O, Boyer TD. Hepatology: A textbook of liver disease, 3rd ed. Philadelphia: WB Saunders, 1996:9.)*

The nerve supply to the liver comes from the vagus and phrenic nerves and the sympathetic ganglia originating from cell bodies in the spinal cord that are located between the seventh and the tenth thoracic vertebrae. These merge to accompany the hepatic artery and bile ducts throughout the liver.

Biliary drainage originates at the bile canaliculi, grooves between adjacent hepatocytes, which form ductules that merge to form the intrahepatic bile ducts. These ultimately join to form the right and left hepatic bile ducts, which exit from the liver at the porta hepatis and merge to form the common hepatic duct. The hepatic duct is joined by the cystic duct from the gallbladder to form the common bile duct (see Figure 47-1). The common bile duct then enters the duodenum (usually with the pancreatic duct) at the ampulla of Vater. The duodenal portion of the common bile duct is surrounded by longitudinal and circular muscle fibers that form the sphincter of Oddi. This musculature relaxes when the gallbladder contracts, allowing bile to enter the duodenum; in its normally contracted state, the sphincter prevents reflux of acidic duodenal contents into the bile duct. The gallbladder, located on the undersurface of the right lobe of the liver, is the site for storage and concentration of bile, a complex mixture of bile salts and waste products. In the adult, it averages about 10 cm in length and has a capacity of 30 to 50 mL of bile. Hormonal stimuli initiated by food ingestion cause contraction of the muscular wall of the gallbladder, releasing bile salts into the intestine to facilitate digestion of fat.

Microscopic Anatomy

The functional anatomical unit of the liver is the acinus, adjacent to the portal triad, which consists of a branch of the portal vein, hepatic artery, and bile duct. Each acinus is a diamond-shaped mass of liver parenchyma that is supplied by a terminal branch of the portal vein and of the hepatic artery and drained by a terminal branch of the bile duct. The blood vessels radiate toward the periphery, forming sinusoids, which perfuse the liver and ultimately drain into the central (terminal) hepatic vein (Figure 47-2). The sinusoids

are lined by fenestrated endothelial cells (allowing free filtration of blood) and phagocytic Kupffer cells (see Figure 47-1). The Kupffer cells are derived from blood monocytes. They contain lysosomes with hydrolytic enzymes that break down phagocytized foreign particles, such as bacteria. They also have immunoglobulins and complement receptors and are the main site for clearance of antigen-antibody complexes from blood. Kupffer cells secrete interleukins, tumor necrosis factor, collagenase, prostaglandins, and other factors involved in the inflammatory response (see Chapter 22).

The major functioning cells in the liver are the hepatocytes, responsible for about 70% of liver mass and performing most of the metabolic and synthetic functions of the liver. Two other cell types are found in small numbers within the liver. The stellate cells (sometimes referred to as Ito cells) are located between the endothelial lining of sinusoids and the hepatocytes within a small cleft referred to as the space of Disse. In their normal, quiescent state, stellate cells serve as a site of storage for fat soluble vitamins, particularly vitamin A. When stimulated, stellate cells are transformed both morphologically and functionally. They synthesize collagen, and are the cells responsible for fibrosis and, eventually, cirrhosis. They synthesize nitric oxide, which helps to regulate intrahepatic blood flow.

The blood supply to each acinus consists of three zones (Figure 47-3). Zone 1 is the area immediately adjacent to the portal tract and is enriched with lysosomes and mitochondria. The periphery of the acinus, zone 3, is enriched with endoplasmic reticulum, is very active metabolically, and has relatively low oxygen tension. This area is most susceptible to injury, although zone 1 appears to be involved with protecting the liver from external injury and providing a base for hepatic regeneration (by means of the oval cells of periportal bile ductules, the apparent hepatic stem cells).

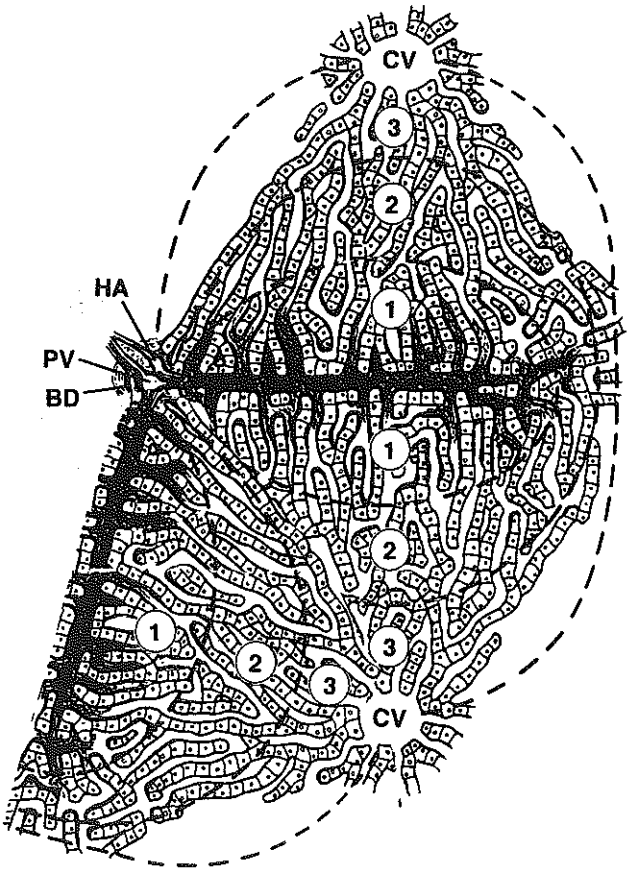

Figure 47-3 Blood supply of the simple liver acinus. *Zones 1, 2,* and *3* indicate corresponding volumes in a portion of an adjacent acinar unit. Oxygen tension and the nutrient level in the blood in sinusoids decrease from zone 1 through zone 3. *BD,* Bile duct; *HA,* hepatic artery; *PV,* portal vein; *CV,* central vein. *(From Zakim O, Boyer TD. Hepatology: A textbook of liver disease, 3rd ed. Philadelphia: WB Saunders, 1996:10.)*

Ultrastructure of the Hepatocyte

Hepatocytes contain a well-developed organelle substructure (Figure 47-4). Mitochondria, which constitute approximately 18% of hepatocyte volume, are the site of oxidative phosphorylation and energy production. They contain enzymes involved in the citric acid cycle and β-oxidation of fatty acids. The rough endoplasmic reticulum is the site of synthesis of many proteins, including albumin, coagulation factors, enzymes (e.g., glucose-6-phosphatase), and triglycerides. The smooth endoplasmic reticulum contains microsomes that are involved with bilirubin conjugation, detoxification (cytochrome P_{450}–dependent isoenzymes), steroid synthesis, cholesterol synthesis, and bile acid synthesis. Many microsomal enzymes, including γ-glutamyl transferase, are induced by many drugs and inhibited by others. This is the site of most drug metabolism and many important drug interactions.

Peroxisomes are found near the smooth endoplasmic reticulum and contain oxidases that use molecular oxygen to modify a variety of substrates, leading to the production of hydrogen peroxide. They also contain catalase, which decomposes hydrogen peroxide. Peroxisomes also catalyze the β-oxidation of fatty acids with chain lengths from 7 to 18. Approximately 5% to 20% of the metabolism of ethanol also occurs in the peroxisomes. Lysosomes are dense organelles that contain hydrolytic enzymes that act as scavengers. Deposition of iron, lipofuscin, bile pigments, and copper occurs in the lysosomes. The Golgi apparatus lies near the canaliculus and is involved with the secretion of various substances, including bile acids and albumin.

BIOCHEMICAL FUNCTIONS OF THE LIVER

The liver is involved in a number of excretory, synthetic, and metabolic functions. Clinical laboratories perform a number of tests that are useful in the biochemical assessment of these functions.

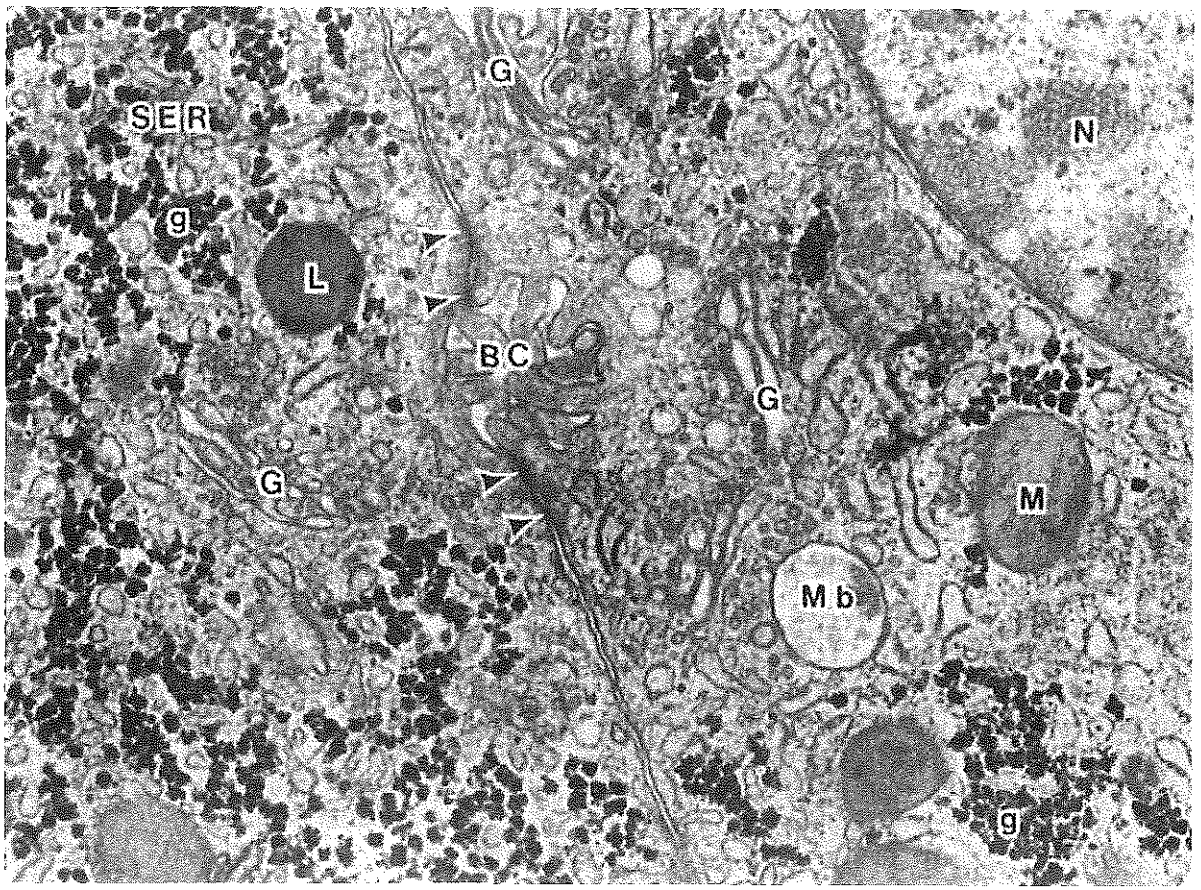

Figure 47-4 Portions of two human liver cells showing the relationship of the organelles and a typical bile canaliculus (BC). *Arrowheads* indicate light junctions. *N,* Nucleus; *M,* mitochondria; *Mb,* microbody; *G,* Golgi; *SER,* smooth endoplasmic reticulum; *L,* lysosome; *g,* glycogen. *(From Zakim O, Boyer TD. Hepatology: A textbook of liver disease, 3rd ed. Philadelphia: WB Saunders, 1996:20.)*

Hepatic Excretory Function

Organic anions of both endogenous and exogenous origin are extracted from the sinusoidal blood, biotransformed, and excreted into the bile or urine. Assessment of this excretory function provides valuable clinical information. The most frequently used tests involve the measurement of plasma concentrations of endogenously produced compounds, such as bilirubin and bile acids, and determination of the rate of clearance of exogenous compounds, such as aminopyrine, lidocaine, and caffeine.

Bilirubin

Bilirubin is the orange-yellow pigment derived from red blood cell turnover. It is extracted and biotransformed in the liver and excreted in bile and urine. The chemistry, biochemistry, and analytical methodology for bilirubin and related compounds are discussed in Chapter 31; a brief overview of factors relevant to understanding of liver disease is included here.

Bilirubin is transported from sites of production (mainly the spleen), loosely bound to albumin, in its native, unconjugated form. Bilirubin is transported across the hepatocyte membrane and is rapidly conjugated with glucuronic acid to produce bilirubin glucuronides, which are then excreted into bile by an energy-dependent process. This process is highly efficient, and bilirubin conjugates are detectable in normal plasma only using highly sensitive techniques. In the presence of bilirubin monoglucuronide, albumin (and other proteins) can be postsynthetically modified by covalent attachment to lysine residues. In the case of albumin, this produces a protein-bound form termed biliprotein or δ-bilirubin. Increases in conjugated bilirubin or δ-bilirubin are highly specific markers of hepatic dysfunction (except in the presence of rare inherited disorders impairing excretion of conjugated bilirubin, such as Dubin-Johnson syndrome). In the intestinal tract, bilirubin glucuronides are hydrolyzed and reduced by bacteria to form colorless *urobilinogens,* which undergo an enterohepatic circulation. A small fraction (2% to 5%) escapes the liver and is excreted in urine. In the colon, urobilinogens spontaneously oxidize to stool pigments stercobilin, mesobilin, and urobilin.

Deviations from normal physiology form the basis for use of laboratory tests of bilirubin metabolism to detect liver

disease. Increased plasma bilirubin is typically classified as primarily indirect (an approximation of unconjugated bilirubin) or direct (an approximation of the sum of conjugated bilirubin and biliprotein). Increased indirect bilirubin indicates either overproduction of bilirubin, usually caused by hemolysis, or decreased extraction by the liver (primarily because of congenital defects involving uridine 5′-phosphate (UDP)-glucuronyl transferase). With severe liver injury, as occurs with fulminant hepatic failure and end stage cirrhosis, liver disease may cause primarily unconjugated hyperbilirubinemia. Increased urine urobilinogen occurs when there is increased bilirubin delivery to the intestinal tract (such as with hemolysis, or following recovery from hepatitis or obstruction), or decreased liver clearance, as occurs in portal hypertension.

Increased direct bilirubin generally results from functional or mechanical impairment in bilirubin excretion from the hepatocyte. Increased conjugated bilirubin is found in most cases of acute hepatitis and cholestasis (stoppage or suppression of the flow of bile); the percentage of direct bilirubin is similar in both types of liver disease.[55] Urine bilirubin is typically present in the presence of increased conjugated bilirubin. With resolution of liver disease, conjugated bilirubin is rapidly cleared, and biliprotein may become the only form present; urine bilirubin is typically absent in such circumstances. Increased conjugated bilirubin is also rarely seen with congenital defects in bilirubin excretion, such as Dubin-Johnson syndrome, and with impaired bilirubin excretion as occurs in sepsis or other acute illness.

Bile Acids

The regulation of bile acid metabolism is a major function of the liver. Alterations in bile acid metabolism are usually a reflection of liver dysfunction. Cholesterol homeostasis is in large part maintained by the conversion of cholesterol to bile acids and subsequent regulation of bile acid metabolism. Bile acids themselves provide surface-active detergent molecules that facilitate both hepatic excretion of cholesterol and solubilization of lipids for intestinal absorption. Bile acid homeostasis requires normal terminal ileum function to absorb bile acids for recirculation (enterohepatic circulation). Alterations in hepatic bile acid synthesis, intracellular metabolism, excretion, intestinal absorption, or plasma extraction are reflected in derangements in bile acid metabolism.

Chemistry

There are four major bile acids (see Figures 47-5 to 47-7). Cholic acid and chenodeoxycholic acid, the primary bile acids, are synthesized in the liver. Bacteria metabolize these primary bile acids to the secondary bile acids—deoxycholic acid and lithocholic acid, respectively. Bile acids are conjugated in the liver with the amino acids glycine or taurine. This decreases passive absorption in the biliary tree and proximal small intestine, but permits conservation through active transport in the terminal ileum. This combination of nonionic transport in the small intestine and active transport in the terminal ileum maintains the bile acid pool. This pool, along with further bile acid synthesis from cholesterol, allows for the continuous solubilization and elimination of cholesterol. Approximately 0.1 to 0.6 g of bile acids is lost in the feces daily.

Biochemistry

Synthesis of Bile Acids. The sequence of reactions involved in the synthesis of cholic acid from cholesterol is shown in Figure 47-5 and includes (1) addition of a hydroxyl group in the 7-α-position, with subsequent further hydroxylation at the 12-α-position; (2) inversion of the hydroxyl group from the 3-β-position (above the plane of the molecule) to the 3-α-position (below this plane); (3) saturation of the double bond at position 5-6; (4) loss of a 3-carbon group from the cholesterol side chain, giving rise to a 24-carbon molecule; and (5) oxidation of the C-24 carbon to a carboxyl group. The other primary bile acid formed in the liver, chenodeoxycholic acid, differs from cholic acid only by the absence of a hydroxyl group at position 12. The initial step in the synthesis of both bile acids, 7-α-hydroxylation of cholesterol, occurs under the influence of the rate-limiting enzyme 7-α-hydroxylase. The reaction is subject to feedback inhibition by bile acids returning to the liver from the ileum.

Before secretion into canaliculi, the primary bile acids are conjugated at the carboxylic acid carbon with either taurine or glycine (Figure 47-6), increasing water solubility. Through this mechanism of conjugation, four primary bile acids (cholyltaurine, cholylglycine, chenodeoxycholyltaurine, and chenodeoxycholylglycine) are formed. Conjugation decreases the pK_a values from ~6 to 4 for glycine conjugates and to 2 for taurine conjugates. Thus conjugated bile acids are in the ionized form in the relatively high pH of the intestinal lumen. In health, the glycine conjugates predominate in a ratio of approximately 3:1 to 4:1. Unconjugated (free) bile acids are not present in bile except in certain pathological states of bacterial overgrowth or ileal resection when intestinal bacteria either dehydroxylate or deconjugate the bile acids.

During passage through the small intestine and colon, both cholic acid and chenodeoxycholic acid are dehydroxylated by bacterial 7-α-dehydroxylase, giving rise to the secondary bile acids deoxycholic acid and lithocholic acid (Figure 47-7). The usual bile acid composition of normal human bile is ~38% cholate conjugates, 34% chenodeoxycholate conjugates, 28% deoxycholate conjugates, and 1% to 2% lithocholate conjugates.

Hepatic Bile Formation. Carrier-mediated active transport of bile acids across the canalicular surface generates osmotic water flow that is a major factor regulating bile formation and secretion. Transport of these organic anions also influences secretion of the remainder of the major components of bile, such as bilirubin, cholesterol, and phospholipids. There is no secretion of the latter two compounds in the absence of bile acid secretion. The influence of bile acid

secretion on biliary lipid excretion is a result of the ability of bile acids to solubilize cholesterol and phospholipids in an aqueous medium in mixed micelles.

Bile formation occurs by processes that are not fully defined. It takes place in canaliculi, minute passages lined by specialized modifications of the hepatocyte membrane, that ultimately unite to form bile ductules. Hepatic bile contains 5% to 15% total solids, the major component of which is bile acids. The increase in biliary water and electrolyte excretion caused by this osmotic effect represents the bile acid–dependent fraction of bile flow. Even with severe depletion of the circulating bile acid pool, as is seen with bile duct diversion, some bile flow continues. The active transport of sodium and of glutathione and bicarbonate is mediated by Na-K-ATPase, which is responsible for the bile acid-independent flow of bile (up to 40% of total flow). Hormones such as secretin increase bile flow by stimulating secretion of sodium, bicarbonate, and chloride. Hormone-dependent flow accounts for 20% to 25% of the total.

Because they possess both polar and nonpolar regions, molecules of bile acids are able to solubilize biliary lipids. Such molecules align at water-lipid interfaces and reduce surface tension, acting as detergents. In an aqueous solution, bile acids aggregate to form small polymolecular aggregates ~5 nm in diameter called *micelles.* These are capable of incorporating cholesterol and phospholipids, forming mixed micelles (Figure 47-8). Micellar solubilization of these water insoluble constituents maintains cholesterol in solution.

Physiology

Enterohepatic Circulation of Bile Acids. The body conserves the bile acid pool through a recirculating system known as the *enterohepatic circulation.* The anatomical components of the enterohepatic circulation are the liver, biliary tract, terminal ileum, and portal venous circulation.

During fasting, bile acids pass down the biliary tree to enter the gallbladder (Figure 47-9). In the gallbladder, they

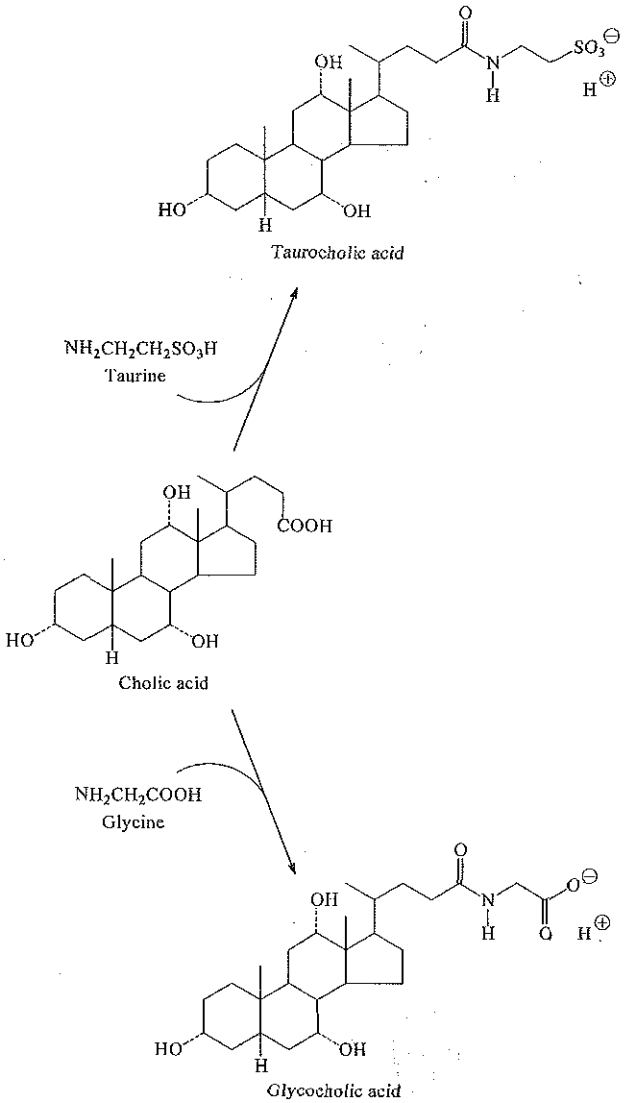

Figure 47-6 Conjugation of cholic acid with either taurine or glycine.

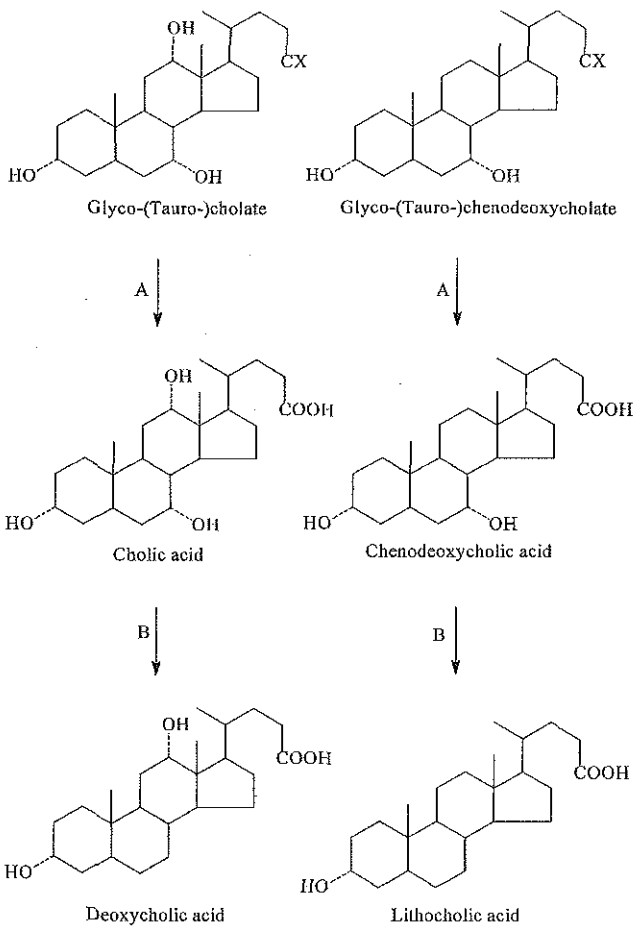

Figure 47-7 Conversion of primary bile acids to secondary bile acids by endogenous microflora.

undergo a tenfold increase in concentration owing to reabsorption of water and electrolytes. After an overnight fast, 95% of the bile acid pool may be sequestered in the gallbladder. This sequestration results in low concentrations of bile acids in the intestine, portal vein, liver, and plasma.

In response to a meal, cholecystokinin is released from the intestine and causes relaxation of the sphincter of Oddi and contraction of the gallbladder (see Chapter 48). This allows a concentrated solution of micelles (consisting of bile salts, lecithin, and cholesterol) to enter the intestine. In the intestinal lumen, dietary cholesterol and the products of triglyceride digestion (predominantly free fatty acids and monoglycerides) are incorporated into mixed micelles. *Micelles deliver lipolytic products to the mucosal surface.* To carry out these functions, a critical micellar bile acid concentration of ~2 mmol/L is necessary.

After delivery of lipids, bile acids are subsequently reabsorbed in the intestine by two mechanisms: active transport in the distal portion of the ileum and nonionic diffusion in the jejunum and colon.

Bile acids are carried in plasma tightly bound to protein. The concentration of bile acids in the portal vein is high but, because of the efficiency of hepatic extraction, systemic *blood concentrations remain low. In a single pass through* the liver, the efficiency of extraction is ~80% for cholic acid and ~60% for chenodeoxycholic acid. Hepatic extraction efficiency is unchanged over a broad range of portal bile acid concentrations.

Kinetics of Bile Acid Metabolism. Using an isotope dilution technique, the bile acid pool in normal adults has been found to average from 2 to 4 g. Steady state is reached when hepatic synthesis and fecal loss are in balance. In health, the magnitude of each process is 0.3 to 0.8 g/day. There are usually 4 to 10 enterohepatic cycles per day. Because of this recycling mechanism, the jejunal concentration of bile acids is maintained at ~5 to 10 mmol/L during the postprandial *state, much higher than the critical micellar concentration* of ~2 mmol/L. Between meals, with decreased entry of bile acids into the intestine, the intraluminal concentration

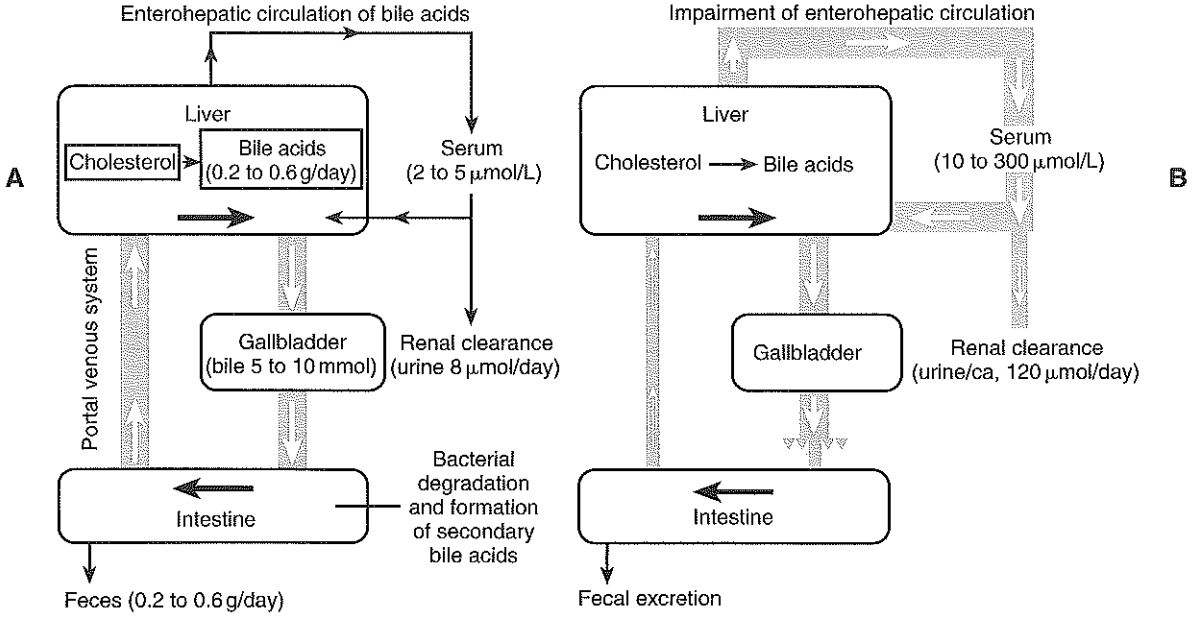

Figure 47-9 Enterohepatic circulation of bile acids. **A,** Normal circulation; **B,** impaired circulation.

decreases. Plasma bile acid concentrations depend on input from the enterohepatic circulation; therefore concentrations of total plasma bile acids will increase by 50% above fasting values 90 to 120 minutes following a meal.

Abnormalities of Bile Acid Metabolism

In view of the multiple processes involved in bile acid synthesis, conjugation, and excretion, and in their hepatic and intestinal uptake, there are several potential sites for primary or secondary disturbances (Box 47-1).

Defective Bile Acid Synthesis. Specific defects in bile acid synthesis have long been postulated. Two inborn errors of bile acid synthesis, both associated with idiopathic neonatal hepatitis, Δ^4-3-oxosteroid 5-β-reductase deficiency and 3-β-hydroxy-dehydrogenase isomerase deficiency, have been described.[37] A third disorder associated with defective bile

BOX 47-1 Disturbances in Bile Acid Metabolism

Defective Bile Acid Synthesis
- *Specific* defects in bile acid synthesis
  - Cerebrotendinous xanthomatosis
  - Intrahepatic cholestasis (familial neonatal hepatitis)
    - 3-β-hydroxysteroid dehydrogenase/isomerase deficiency
    - Δ^4-3-oxosteroid 5-β-reductase deficiency
    - C_{24} steroid: 7-α-hydroxylase deficiency
  - Peroxisomal disorders
    - Genetic diseases with a general impairment of numerous peroxisomal functions and reduced or undetectable peroxisome numbers
      - Cerebrohepatorenal (Zellweger's) syndrome
      - Infantile Refsum's disease
      - Neonatal adrenoleukodystrophy
      - Rhizomelic chondrodysplasia punctata
      - Hyperpipecolic acidemia
    - Genetic diseases with generalized impairment of peroxisomal function but normal number of peroxisomes
      - Pseudo-Zellweger's syndrome
    - Genetic diseases with a single enzyme defect and a normal number of peroxisomes
      - X-linked adrenoleukodystrophy
      - Adult Refsum's disease
      - Acatalasemia
- *Acquired* defects in bile acid synthesis (nonspecific) secondary to parenchymal liver disease (cholestasis, cirrhosis)

Abnormalities of Bile Acid Delivery to the Bowel
- Celiac sprue

Extrahepatic Bile Duct Obstruction
- Congenital biliary atresia
- Stricture
- Stone
- Carcinoma

Interruption of the Enterohepatic Circulation of Bile Acids
- External bile drainage (fistula)
- Ileojejunal exclusion for exogenous obesity or hypercholesterolemia
- Cystic fibrosis
- Contaminated small bowel syndrome (with bile acid precipitation, increased jejunal absorption, and "short circuiting")
- Entrapment of bile acids in intestinal lumen by:
  - Cholestyramine
  - Trivalent cations
  - Fiber

Bile Acid Malabsorption
- Primary bile acid malabsorption (absent or inefficient ileal active transport)
  - Intractable diarrhea (infancy)
  - Irritable bowel (adults)
- Secondary bile acid malabsorption
  - Ileal disease or resection
    - Crohn's disease
    - Ileal resection
    - Ileal bypass
    - Radiation enteritis
    - Postinfectious enteritis
  - Exogenous bile acid administration (e.g., gallstone dissolution)
    - Cystic fibrosis
- Tertiary bile acid malabsorption
  - Postcholecystectomy
  - Renal failure
  - Drugs

Defective Uptake or Altered Intracellular Metabolism
- Parenchymal disease (acute hepatitis, cirrhosis) associated with regurgitation from cells or portosystemic shunting
- Cholestasis

acid synthesis is cerebrotendinous xanthomatosis. In this disorder, chenodeoxycholic acid production is affected more than cholic acid production, and unusual metabolites, such as bile alcohols, are present in bile and feces.

In addition to *primary* defects in bile acid synthesis, *secondary* abnormalities have been noted in peroxisomal disorders, such as neonatal adrenoleukodystrophy and cerebrohepatorenal (Zellweger's) syndrome—an autosomal recessive condition associated with severe cholestasis in which side chain oxidation is impaired.

More frequently encountered are *acquired* defects in bile acid synthesis, which have been noted in liver diseases such as hepatitis and cirrhosis. In acute hepatitis, alterations of bile acid synthesis and conjugation occur because of hepatic parenchymal cell disease. In cirrhosis, there is a marked reduction in cholic acid synthesis with a low concentration of biliary deoxycholic acid. These abnormalities are due both to decreased synthesis and to portosystemic shunting. The severity of cirrhosis correlates closely with the loss of cholic acid synthetic capacity. The decreased ratio of the trihydroxy bile acid (cholic acid) to the dihydroxy bile acid (chenodeoxycholic acid) in plasma has therefore been used as a diagnostic test of liver cell dysfunction.

Abnormalities of Bile Acid Delivery to the Bowel. Decreased bile flow from intrahepatic cholestasis or extrahepatic bile duct obstruction caused by biliary atresia, stricture, stone, or carcinoma will result in bile acid retention and regurgitation from the liver cell into plasma and a decrease in delivery to the intestine. The ratio of plasma trihydroxy to dihydroxy acids increases in cholestasis.

Interruption of the Enterohepatic Circulation of Bile Acids. Approximately 95% of the bile acids that are secreted during a single enterohepatic cycle are recirculating bile acids. Therefore a significant interruption of this cycle will lead to a decrease in hepatic bile acid secretion. A negative feedback increase in bile acid synthesis can only partially

compensate for the losses. Therefore resection, inflammation, or bypass of the ileum will be associated with specific clinical symptoms and disturbances of bile acid metabolism. The amount of bile acid return to the liver is reduced, and a loss of feedback inhibition results in accelerated hepatic synthesis of bile acids. The concentration of plasma cholesterol is reduced, since an increased proportion of this compound is used for bile acid synthesis. Concentrations of plasma bile acids decrease and are a reflection of ileal dysfunction, since the expected postprandial rise (due to ileal absorption of bile acids) will not be present.[37]

Disturbances of Bile Acid Metabolism in Hepatocellular Disease. Fasting plasma bile acid concentrations are elevated in hepatocellular diseases, such as hepatitis and cirrhosis. The mechanisms responsible are regurgitation of bile acids from cholestatic hepatocytes and portosystemic shunting. These defects allow the plasma concentrations to rise proportionately much higher than normal following meals, suggesting that the postprandial rise in plasma bile acids may be a sensitive test for the detection of liver disease.

Clinical Significance

Increased plasma bile acid concentrations in the fasting state suggest impaired hepatic uptake or secretion, or portosystemic shunting. Thus, such measurements may be used as a sensitive endogenous clearance test. However, a diagnosis suggested by an increase in plasma bile acid concentrations should be confirmed by standard liver function tests. In a similar manner, abnormal standard liver function tests can be confirmed as indicative of hepatic dysfunction by concomitant measurement of plasma bile acids. Plasma bile acid measurements may also be used serially to monitor patients with suspected or proven hepatic disease. However, they add little to standard tests of liver function and are now rarely used in clinical medicine.

Analytical Methodology

Analytical techniques used to quantify either total or individual bile acids in biological fluids include gas-liquid chromatography (GLC), high-performance liquid chromatography (HPLC), enzymatic assay, radioimmunoassay (RIA), enzyme-linked immunosorbent assay (ELISA), and tandem mass spectrometry (MS/MS).

Hepatic Synthetic Function

The liver has extensive synthetic capacity and plays a major role in the regulation of protein, carbohydrate, and lipid metabolism (see Chapters 20, 25, and 26). A bidirectional flux of precursors and products, such as glucose, amino acids, free fatty acids, and other nutrients, occurs across the hepatocyte membrane. Normal blood glucose concentrations are maintained during short fasts by the breakdown of hepatic glycogen and during prolonged fasts by hepatic gluconeogenesis. The primary sources of carbon atoms for gluconeogenesis are amino acids derived from muscle proteins. To a lesser extent, lactate (produced in skeletal muscle and erythrocytes) and glycerol (obtained from hydrolysis of triglycerides) also serve as substrates for gluconeogenesis. In humans, the oxidation of odd-numbered fatty acids yields propionyl-CoA, which can be converted to glucose. However, the formation of glucose in this manner is not quantitatively significant. Protein, triglyceride, fatty acid, cholesterol, and bile acid synthesis also occur within the liver.

Protein Synthesis

The liver is the primary site of the synthesis of plasma proteins (see Chapter 20). Synthesis occurs in the rough endoplasmic reticulum of the hepatocytes, followed by release into hepatic sinusoids. Although disturbances of protein synthesis occur as a consequence of impaired hepatic function, a variety of other factors also affect plasma protein concentrations. These include (1) decreased availability of amino acids (malnutrition, maldigestion, and malabsorption), (2) catabolic states (hyperthyroidism, Cushing's syndrome, burns, postsurgery recovery), (3) protein losing states (nephrotic syndrome and protein losing enteropathy), (5) actions of cytokines (decrease in transport proteins such as albumin, transferrin, and lipoproteins, but increase in inflammatory response modifiers such as α_1-antitrypsin, haptoglobin, and α_2-macroglobulin), (5) action of hormones (such as growth hormone, cortisol, estrogen, androgens, and thyroid hormones) to increase or decrease production of specific proteins, and (6) congenital deficiency states (Wilson's disease and α_1-antrypsin deficiency). In addition, the liver has a significant reserve capacity, preventing protein concentrations from decreasing unless there is extensive liver damage. In addition, many liver proteins have relatively long half-lives, such as albumin at approximately 3 weeks. For this reason, the sensitivity and specificity of protein concentrations for diagnosis of liver disease are far from ideal.

The patterns of plasma protein alterations seen in liver disease depend on the type, severity, and duration of liver injury. For example, in acute hepatic dysfunction, there is usually little change in the plasma protein profile or the total plasma protein concentration; with fulminant hepatic failure or severe liver injury, concentrations of short-lived hepatic proteins (such as transthyretin and prothrombin) will fall quickly and become abnormal, whereas proteins with longer half-lives will be unchanged. In cirrhosis, concentrations of liver-synthesized plasma proteins and immunoglobulins decrease and increase repectively. Serial determination of plasma proteins provides prognostic information; for example, a worsening of prothrombin time during acute hepatitis suggests a poor prognosis.

Plasma Proteins

Albumin. Albumin is the most commonly measured serum protein and is synthesized exclusively by the liver. The rate of synthesis varies, depending on hormonal environment, nutritional status, age, and other local factors. In inflamma-

tory conditions. Interleukin-6 (IL-6) inhibits albumin synthesis but induces synthesis of acute phase response proteins. With liver disease, hypoalbuminemia is noted primarily in cirrhosis, autoimmune hepatitis, and alcoholic hepatitis. The mechanism is multifactorial. In cirrhosis, hepatic synthesis of albumin may be decreased, normal, or increased. Loss of albumin into ascitic fluid seems responsible for the decrease in albumin in many cases. One important consideration in measurement of albumin is the inaccuracy of dye-binding methods in patients with liver disease. Although bromcresol green measurements tend to overestimate albumin concentration at low concentrations,[290] bromcresol purple methods give falsely low values in patients with jaundice because of interference of bilirubin at the site of binding.[209]

Transthyretin. This protein has a short half-life of 24 to 48 hours, making it a sensitive indicator of current synthetic ability. Failure of transthyretin to increase is an indicator of fulminant hepatic failure in acute hepatitis and is associated with a poor prognosis.[202] It is more commonly used as a measurement of nutritional status.

Immunoglobulins. Immunoglobulins are commonly increased in cirrhosis, autoimmune hepatitis, and primary biliary cirrhosis but are normal in most other types of liver disease. IgG is increased in autoimmune hepatitis and cirrhosis; IgM is increased in primary biliary cirrhosis. IgA tends to be increased in all types of cirrhosis. None of these findings are specific, and they are seldom used in the diagnosis of liver disease.

Ceruloplasmin. This protein is decreased in Wilson's disease, cirrhosis, and many causes of chronic hepatitis, but may be increased by inflammation, cholestasis, hemochromatosis, pregnancy, and estrogen therapy. It is discussed in more detail under Wilson's disease.

α_1-Antitrypsin. This protein is the major serine protease inhibitor (serpin) in plasma, and is decreased in homozygous deficiency and cirrhosis and increased by acute inflammation. It is discussed in more detail later in this chapter under the heading for α_1-antitrypsin deficiency.

α-Fetoprotein. This protein, a normal component of fetal blood, falls to adult concentrations by 1 year of age. Mild increases are seen in patients with acute and chronic hepatitis and indicate hepatocellular regeneration. It is present at higher concentrations in hepatocellular carcinoma (HCC) and is discussed in more detail later and in Chapters 20 and 54.

Coagulation Proteins

The coagulation proteins that are synthesized in the liver are listed in Table 47-1. These proteins interact to produce a fibrin clot. Inhibitors of the coagulation system, including antithrombin, protein C, and protein S, are also synthesized in the liver. Some of the coagulation factors (II, VII, IX, and X) require vitamin K for posttranslational carboxylation within the hepatocyte. Protein C and S are also carboxylated by a vitamin K–dependent enzyme. Activated protein C in plasma inhibits coagulation by inactivating factors V and VIII. Parenchymal liver disease of sufficient severity to impair protein synthesis or obstructive liver disease sufficient to impair intestinal absorption of vitamin K is therefore a potential cause of bleeding disorders. Because of the great functional reserve of the liver, failure of hemostasis usually does not occur except in severe or long-standing liver disease.[237] Thus testing for a coagulation defect is not a screening procedure but rather a means of assessing severity and following the progress of liver disease.

TABLE 47-1 Blood Coagulation Factors

Number or Acronym	Name
I	Fibrinogen*
II	Prothrombin*†
III	Tissue factor
IV	Calcium (Ca^{2+})
V	Proaccelerin*
VI	—
VII	Proconvertin*†
VIII	Antihemophilic factor
IX	Christmas factor*†
X	Stuart-Prower factor†
XI	Plasma thromboplastin antecedent*
XII	Hageman factor*
XIII	Fibrin-stabilizing factor*
PK	Prekallikrein (Fletcher factor)*
HMWK	High molecular weight kininogen*

*Protein synthesized in liver.
†Synthesis requires vitamin K.

The prothrombin time (PT) measures activity of fibrinogen (factor I), prothrombin (factor II), and factors V, VII, and X. Since all of these factors are made in the liver and several are vitamin K dependent, a prolonged PT often indicates the presence of significant liver disease. In cholestasis, vitamin K deficiency may also cause an increase in PT. In this case, the coagulation abnormality is corrected within a few days by parenteral injection of 10 mg of vitamin K. In contrast, if PT is prolonged because of hepatocellular disease, factor synthesis is decreased and administration of vitamin K does not typically correct the problem. PT is also prolonged in some patients with liver disease because of the presence of dysfibrinogenemia, an abnormal form of fibrinogen that does not clot normally, and that may predispose to thrombosis.[158]

The method for reporting PT in liver disease remains controversial. PT measures the time to clot after exposure of plasma to tissue factor. Reagents differ in the amount of tissue factor present; in patients with coagulopathy, clotting times are more greatly prolonged when lower amounts of tissue factor are in the reagents. This makes a reagent more sensitive to clotting factor abnormalities, but makes stan-

dardization of results between laboratories difficult. The International Normalized Ratio (INR) was developed by the World Health Organization (WHO) and the International Committee on Thrombosis and Hemostasis (ICTH) for reporting the results of blood coagulation (clotting) tests. All results are standardized using the international sensitivity index (ISI) for the particular thromboplastin reagent and instrument combination used to perform the test. In practice, it requires determination of the ISI based on the slope of the relationship between prothrombin time using the reagent and that using a reference method in patients on warfarin. The INR is then calculated as:

$$\text{INR} = \left[\frac{\text{PT (patient)}}{\text{PT (geometric mean of normal)}}\right]^{\text{ISI}}$$

INR has been found to standardize interpretation of PT measurements between laboratories in those taking warfarin. Unfortunately, INR does not have the same relationship to impairment of clotting in individuals with liver disease.[224,439] The apparent explanation lies in the mechanism of clotting factor deficiency in liver disease and warfarin administration. Although liver disease inhibits synthesis of clotting factors, warfarin impairs vitamin K–dependent carboxylation, impairing the ability of the factors to bind calcium. These noncarboxylated clotting factors (termed proteins induced by vitamin K antagonists, or PIVKAs) appear to act as inhibitors of coagulation; thus when lower amounts of tissue factor are present, there is greater prolongation of clotting times.[245] In contrast, in liver disease, factor deficiency is due to impaired factor synthesis, and no PIVKAs are present (except in HCC, as discussed later in this chapter). This leads to minimal increases in PT in individuals with liver disease and underestimation of the degree of clotting impairment when reagents with low ISI are used. Although it is not clear which method of reporting PT is ideal, one study has suggested using the prothrombin index (the ratio used in calculation of INR, but without the ISI exponential).[371] However, few data exist on prothrombin indices that indicate significant impairment of coagulation.[113]

Lipid and Lipoprotein Synthesis

The liver plays a key role in the metabolism of lipids and lipoproteins (see Chapter 26). On a daily basis, approximately 33% of the fatty acids originating from adipose tissue enter the liver, where they undergo esterification into triglycerides or are oxidized. Oxidation is favored in the fasting state and esterification is favored in the nonfasting state. Excessive esterification results in "fatty liver," a disorder in which excess triglycerides are deposited in large vacuoles that displace other cellular components. Most cholesterol is endogenously synthesized in the liver. It and cholesterol of dietary origin enter the hepatic pool, where they are converted to bile acids, incorporated into lipoproteins, or used in the synthesis of liver cell membranes. The relative rates of secretion of bile acids, cholesterol, and lecithin are important factors in the pathogenesis of cholesterol gallstones.

Urea Synthesis

Patients with end-stage liver disease may have low concentrations of urea in plasma (see Chapter 45). The rate of urea excretion in urine is lower than in healthy individuals. In addition, plasma concentrations are elevated for urea precursors ammonia and amino acids. Lower specific activities are found for enzymes involved in urea synthesis. These findings suggest that patients with liver disease have an impaired ability to metabolize protein nitrogen and to synthesize urea. The rate of hepatic urea synthesis depends on exogenous intake of nitrogen and on endogenous protein catabolism. Newly synthesized urea equilibrates throughout the total body water compartment and to a large extent is excreted in urine. A small portion diffuses into the intestine, where bacterial enzymes hydrolyze urea to produce ammonia. Carbon dioxide is excreted, whereas ammonia is reabsorbed and must be recycled through the liver. Thus the rate of urea synthesis can be calculated through analysis of urinary urea excretion and the blood urea nitrogen (BUN) level if total body water and the extent of GI hydrolysis of urea can be estimated. In cirrhotic patients, the Krebs-Henseleit pathway is unable to incorporate excess ammonia nitrogen into urea.

Hepatic Metabolic Function

A recurring theme is the central importance of the liver in metabolic and regulatory pathways. The functional expression of the complex, integrated organelle structure includes the metabolism of drugs (activation and detoxification) and the disposal of exogenous and endogenous substances, such as galactose and ammonia. In addition, metabolic abnormalities due to specific, inherited enzyme deficiencies can affect the liver. A classic example is galactosemia. In this condition the congenital absence of the galactose-1-phosphate uridyltransferase enzyme allows accumulation of the toxic metabolite galactose-1-phosphate, which causes injury to the liver, brain, and kidneys.

Ammonia Metabolism

Biochemistry and Physiology

The major source of circulating ammonia is the GI tract. Plasma ammonia concentration in the hepatic portal vein is typically fivefold to tenfold higher than that in the systemic circulation. It is derived from the action of bacterial proteases, ureases, and amine oxidases on the contents of the colon and from the hydrolysis of glutamine in both the small and large intestines. Under normal circumstances, most of the portal vein ammonia load is metabolized to urea in hepatocytes in the Krebs-Henseleit urea cycle during the first pass through the liver; this process includes intramitochondrial and cytosolic enzyme-catalyzed steps (Figure 47-10).

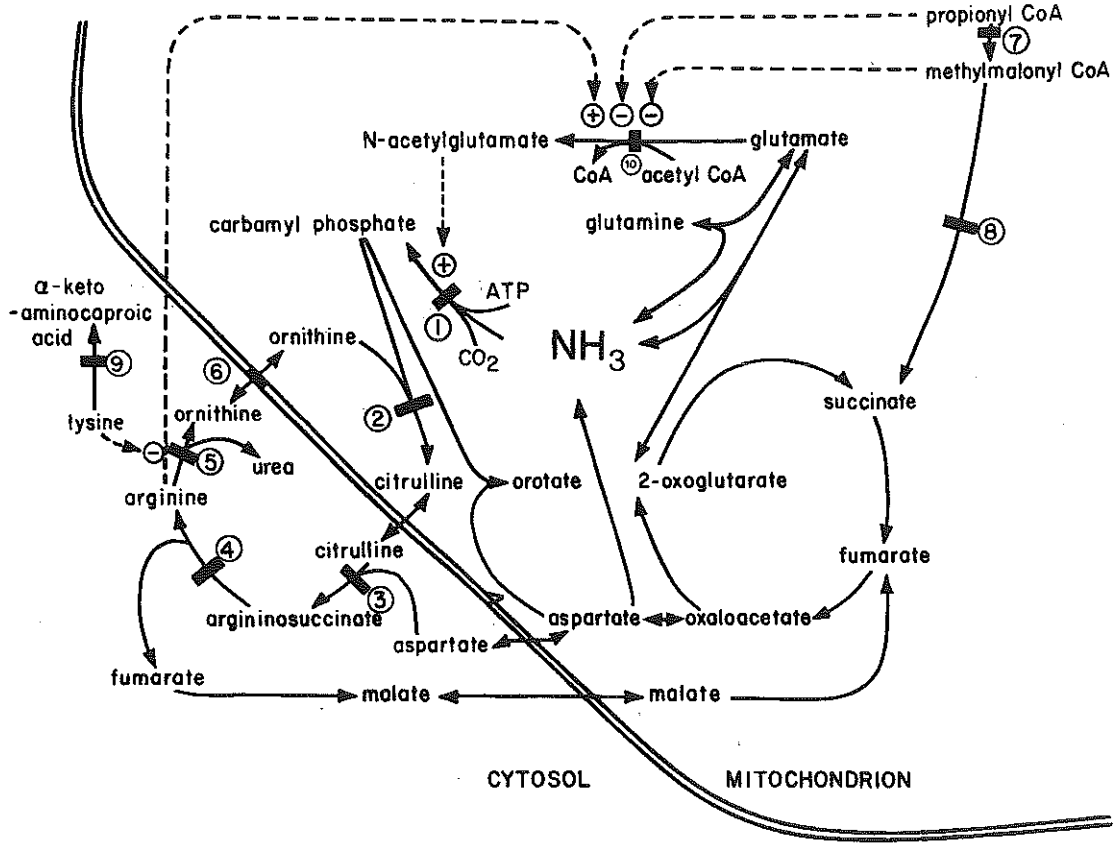

Figure 47-10 The major metabolic pathways for the use of ammonia by the hepatocyte. *Solid bars* indicate the sites of primary enzyme defects in various metabolic disorders associated with hyperammonemia: (*1*) carbamyl phosphate synthetase I, (*2*) ornithine transcarbamylase, (*3*) argininosuccinate synthetase, (*4*) argininosuccinate lyase, (*5*) arginase, (*6*) mitochondrial ornithine transport, (*7*) propionyl CoA carboxylase, (*8*) methylmalonyl CoA mutase, (*9*) L-lysine dehydrogenase, and (*10*) *N*-acetyl glutamine synthetase. *Dotted lines* indicate the site of pathway activation (+) or inhibition (–). *(From Flannery OB, Hsia YE, Wolf B. Current status of hyperammonemia syndromes. Hepatology 1982; 2:495-506.)*

Ammonia enters tissue of the central nervous system by passive diffusion. The rate of entry increases in proportion to the plasma concentration and is dependent on pH. As pH increases, the rate of entry of ammonia into the central nervous system tissue increases. This is thought to be because an increase in pH produces a shift to the right in the equilibrium

$$NH_4^{\oplus} + H_2O \rightleftharpoons NH_3 + H_3O^{\oplus}$$

that results in an increased ammonia base concentration. Ammonia crosses the blood-brain barrier membranes more readily than the ammonium ion. Given that the pK_a of ammonia is 8.9 at 37°C, approximately 3% of blood ammonia is NH_3 at the normal physiological pH of 7.4. An increase of pH to 7.6 produces an increase in NH_3 to approximately 5% of total blood ammonia—a 67% increase in concentration.

Clinical Significance

Animal and human studies have shown that an elevated concentration of ammonia (hyperammonemia) exerts toxic effects on the central nervous system. There are several causes, both inherited and acquired, of hyperammonemia. The inherited deficiencies of urea cycle enzymes are the major cause of hyperammonemia in infants.[66] The two major inherited disorders are those involving the metabolism of the dibasic amino acids lysine and ornithine and those involving the metabolism of organic acids, such as propionic acid, methylmalonic acid, isovaleric acid, and others (see Chapter 55).

The acquired causes of hyperammonemia are advanced liver disease and renal failure. Severe or chronic liver failure (as occurs in fulminant hepatitis and cirrhosis, respectively) leads to a significant impairment of normal ammonia metabolism. Reye's syndrome, which is primarily a central nervous system disorder with minor hepatic dysfunction, is also associated with hyperammonemia. Hepatic en-

cephalopathy, in the cirrhotic patient, is often precipitated by GI bleeding that enhances ammonia production by bacterial metabolism of the blood proteins in the colon and subsequent increases in blood ammonia concentrations. Other precipitating causes of encephalopathy include excess dietary protein, constipation, infections, drugs, or electrolyte and acid-base imbalance. Since cirrhosis is accompanied by portosystemic shunting, ammonia clearance is impaired, leading to increased concentrations of blood ammonia. Impaired renal function also causes hyperammonemia. As BUN concentration increases, more diffuses into the GI tract where is it converted to ammonia.

The fasting venous plasma ammonia concentration is useful in the differential diagnosis of encephalopathy when it is unclear if encephalopathy is of an hepatic origin. It is especially helpful in diagnosing Reye's syndrome and the inherited disorders of urea metabolism. However, it is not a useful test to use in patients with known liver disease.

Analytical Methodology

Both enzymatic and chemical methods are used to measure ammonia in body fluids. Enzymatic assay with glutamate dehydrogenase is the most frequently used method. Plasma ammonia measurement is particularly susceptible to contamination, leading to falsely elevated concentrations. Some of the common sampling problems are discussed in the third edition of this textbook.

Reference Intervals

For the enzymatic method, the reference interval is 15 to 45 μg N/dL or 11 to 32 μmol N/L. Should values in normal subjects be much higher than expected, consideration should be given to the existence and correction of sources of preanalytical error resulting from contamination.

Carbohydrate Metabolism

Because the liver is a major processor of dietary and endogenous carbohydrates, liver disease affects carbohydrate metabolism in a variety of ways (see Chapter 25). However, none of the conventional modes of evaluating carbohydrate metabolism have value in the diagnosis of liver disease. Because the liver is the major site of both glycogen storage and gluconeogenesis, hypoglycemia is a common complication in certain liver diseases, particularly Reye's syndrome, fulminant hepatic failure, advanced cirrhosis, and hepatocellular carcinoma.

Xenobiotic Metabolism and Excretion

Xenobiotics are foreign substances that are cleared and metabolized by the liver and some have been used as tests of liver function. For example, certain lipophilic substances such as bromsulfophthalein (BSP), indocyanine green (ICG), aminopyrine, caffeine, lidocaine, and rose bengal are excreted into bile as the intact parent compound, its conjugates, or both. The clearance of these xenobiotics by the liver is normally very rapid, and it is believed that uptake by hepatocytes is a carrier-mediated, active-transport process. Little, if any, is cleared by other tissue. Excretion into bile is slow. The elimination of these compounds from the bloodstream therefore depends on hepatic blood flow, patency of the biliary tree, and hepatic parenchymal function.

Dye Excretion Tests

Dye excretion tests (such as BSP and ICG clearance) were formerly used as indicators of liver disease. With the development of more sensitive and specific indicators of liver disease, dye excretion tests have become obsolete. Until the 1970s, BSP was the most frequently used dye excretion test. Because of reports of fatalities resulting from hypersensitivity and other adverse effects (nausea, syncope, headache, chills, and thrombophlebitis at the site of injection), BSP use has been discontinued. ICG clearance was used for investigation of hepatic blood flow and for predicting clearance rates of drugs that undergo first-pass clearance by the liver, such as lidocaine. Typical ICG clearance values in healthy subjects range from 6.5 to 14 mL/min/kg. ICG clearance is still occasionally used.

Drug Clearance Tests

A variety of drugs that are metabolized by the liver have been used to study the action of various P_{450} enzymes. *Aminopyrine* is demethylated to form carbon dioxide and aminoantipyrine. By using ^{14}C-labeled aminopyrine, the resulting $^{14}CO_2$ can be measured in breath as a reflection of functioning liver mass.[195] There is significant interindividual and intraindividual variation in results,[76,352] other microsomal enzyme inducing agents increase metabolism,[76] and overall diagnostic sensitivity is similar to that of other more routine laboratory tests.[331] *Caffeine* is rapidly and nearly completely absorbed from the GI tract and then undergoes N-demethylation by the hepatic mixed-function oxidase system. Caffeine clearance is altered during hepatic injury, being prolonged in both chronic hepatitis and cirrhosis.[469] A single dose of caffeine (3.5 mg/kg to a maximum dose of 200 mg, dissolved in either water, fruit juice, or milk for oral administration) is administered. This caffeine dose is equivalent to that found in one cup of brewed coffee or in one can of commercial soft drink. Blood (or salivary samples) obtained before and at timed intervals after caffeine ingestion can be analyzed by reversed-phase HPLC or immunoassay. A close correlation is found between plasma and salivary caffeine concentrations. Caffeine half-life is approximately 5.5 hours in healthy adults and 3 hours in healthy children, with clearance of approximately 2 mL/min/kg in healthy adults and 10 mL/min/kg in healthy children. Caffeine clearance correlates with the aminopyrine breath test and has similar limitations, although it is less subject to effects of variables, such as smoking and oral contraceptive use.[76] *Lidocaine* undergoes N-deethylation in the liver by cytochrome P_{450} to form monoethylglycinexylidide (MEGX); the rate of appearance of MEGX in plasma reflects hepatic lidocaine clearance. Because lidocaine is highly extracted, its clearance

is flow-dependent. Thus alterations in hepatic blood flow also influence lidocaine elimination.[493] Lidocaine (1 mg/kg) is given by intravenous bolus; plasma is obtained at baseline and 15 minutes for MEGX concentration (time of plateau concentration in healthy individuals). MEGX is most commonly measured using immunoassay. Lidocaine clearance has been used to assess liver transplant function, but its use is limited by the effect of hypoperfusion (as occurs in sepsis or volume depletion).[165]

Hepatic Storage Function

Because individual cells are unable to store a sufficient supply of energy-rich carbohydrate substrates, the liver serves as the major site for their storage. For example, hepatic storage of glycogen allows the release of glucose to other tissue when the need exists (e.g., when plasma concentrations of glucose decrease). Other tissues, such as muscle and adipose tissue, store proteins and triglycerides, respectively, and are capable of adaptation. Depending on the availability of oxidizable fuels, these tissues also switch from the storage mode to the synthesis or release modes during periods of decreased carbohydrate intake.

CLINICAL MANIFESTATIONS OF LIVER DISEASE

A number of conditions are indicative of liver disease including (1) jaundice, (2) portal hypertension, (3) abnormal hepatorenal function, (4) altered drug metabolism, (5) nutritional and metabolic abnormalities, (6) disordered hemostasis, and (7) the release of enzymes into various body fluids.

Jaundice

Jaundice (or icterus) is a physical sign characterized by a yellow appearance of the skin, mucous membranes, and sclera caused by bilirubin deposition. It is the most specific clinical manifestation of hepatic dysfunction, but is not present in many individuals with liver disease (especially chronic liver disease), and may occur in states of bilirubin overproduction (such as hemolysis). Jaundice is most easily seen in the sclera of the eyes, where yellow contrasts sharply with the usual bright white color. Jaundice is usually apparent clinically when the plasma bilirubin concentration reaches 2 to 3 mg/dL (34 to 51 μmol/L), although higher concentrations may be required when fluorescent lighting is used. When bilirubin clearance from the liver to the intestinal tract is impaired (as in acute hepatitis and bile duct obstruction), it may be accompanied by acholic (gray-colored) stools. Bilirubin is the source of stercobilin, which produces the brown color of normal stool. Increases in plasma conjugated bilirubin lead to tea-colored urine, since conjugated bilirubin is water soluble. Jaundice may also be due to disorders of bilirubin metabolism. Bilirubin metabolism is discussed more fully in Chapter 31. A classification of jaundice, based on the site of altered bilirubin metabolism, is shown in Box 31-1.

Portal Hypertension

The portal circulation handles all of the venous outflow of the GI tract, the spleen, the pancreas, and the gallbladder (Figure 47-11). The portal vein is formed by the union of the splenic vein and the superior mesenteric vein. Portal flow is normally 1000 to 1200 mL/min with a pressure of 5 to 7 mm

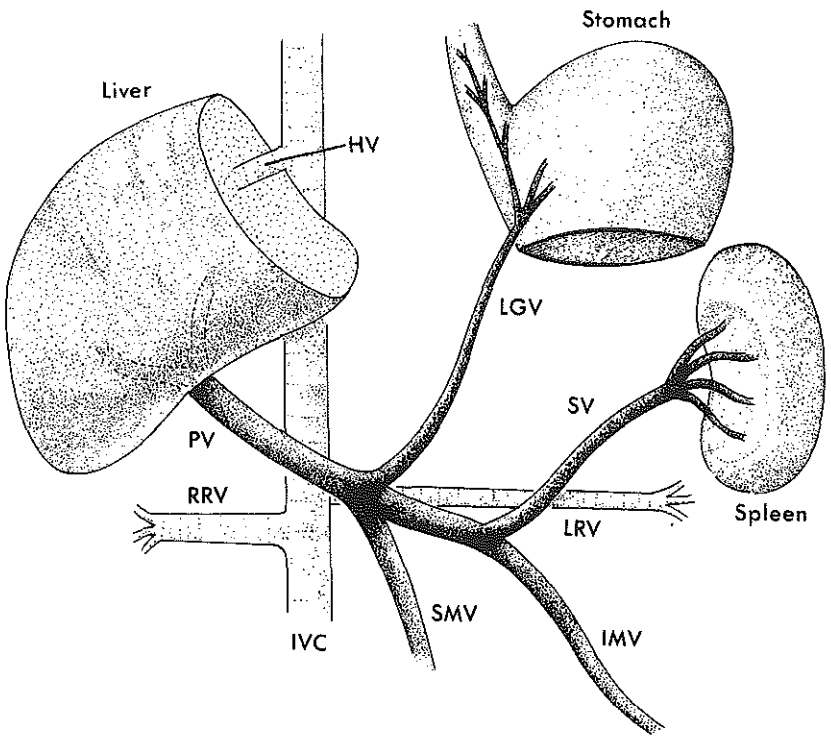

Figure 47-11 The portal-venous system. *HV,* Hepatic vein; *IVC,* inferior vena cava; *IMV,* inferior mesenteric vein; *LGV,* left gastric vein; *LRV,* left renal vein; *PV,* portal vein; *RRV,* right renal vein; *SV,* splenic vein; *SMV,* superior mesenteric vein. *(From Zakim O, Boyer TD. Hepatology: A textbook of liver disease, 3rd ed. Philadelphia: WB Saunders, 1996:721.)*

Hg. Portal hypertension occurs when there is obstruction to portal flow anywhere along its course. The causes of obstruction leading to portal hypertension are classified by site: (1) presinusoidal, (2) sinusoidal, and (3) postsinusoidal. Presinusoidal portal hypertension is most commonly caused by portal vein thrombosis or schistosomiasis but may also occur with increased portal flow, such as occurs with Felty syndrome (a combination of chronic rheumatoid arthritis, splenomegaly, leukopenia, pigmented spots on the lower extremities, and sometimes other evidence of hypersplenism, such as anemia and thrombocytopenia). Sinusoidal hypertension is most commonly caused by cirrhosis but may occur transiently with acute and chronic hepatitis or acute fatty liver. The most important cause of postsinusoidal hypertension is hepatic vein occlusion or Budd-Chiari syndrome, in which sudden obstruction or occlusion of the hepatic veins causes hepatomegaly, abdominal pain, severe ascites, mild jaundice, and eventually portal hypertension and liver failure. The most common cause of postsinusoidal hypertension is cardiac disease, most commonly congestive heart failure. Chronic congestive heart failure is usually associated with portal hypertension and ascites, and may even lead to increased activities of aminotransferases.[317] Other causes include abscesses, membranous obstruction of the vena cava, and veno-occlusive disease (as may be seen in patients following bone marrow transplantation). Although increased portal resistance is the major factor causing portal hypertension, it is often accompanied by decreased resistance to blood flow through other blood vessels, which increases blood flow through the portal veins.

When portal pressure increases, the portal venous system becomes dilated and forms collateral connections to the sys-

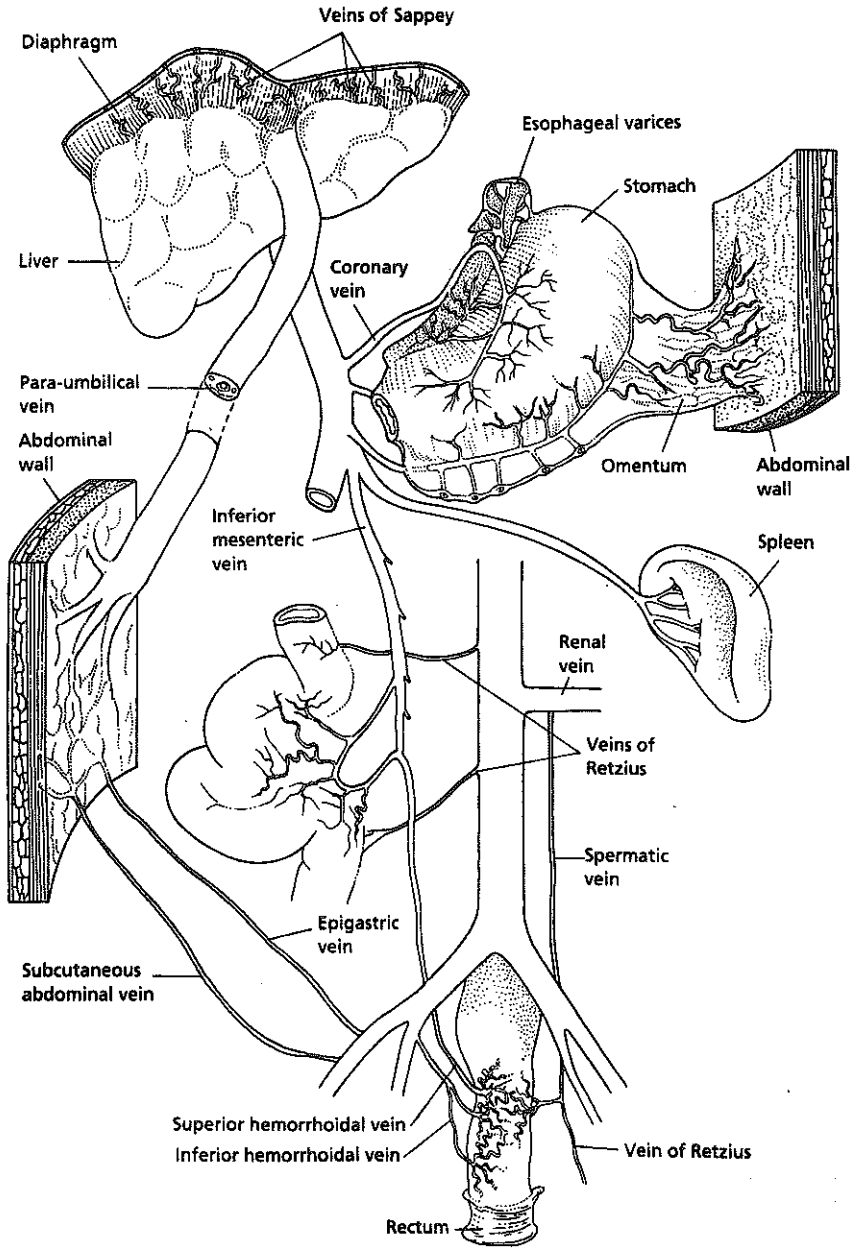

Figure 47-12 The sites of the portosystemic collateral circulation in cirrhosis of the liver. *(From Sherlock S, Dooley J, eds. Diseases of the liver and biliary system, 9th ed. London: Blackwell Scientific Publications, 1993:134.)*

temic venous flow (Figure 47-12), leading to portosystemic shunting. Initially, this is clinically silent, but as portal hypertension worsens, it compromises many of the metabolic functions of the liver. One such abnormality is altered estrogen metabolism, increasing the ratio of estrogen to testosterone. Clinical consequences include spider telangiectasias and palmar erythema, gynecomastia (in men), and abnormal vaginal bleeding and irregular menstrual periods (in women). Impaired protein metabolic functions lead to the accumulation of ammonia and abnormal neurotransmitters, ultimately leading to hepatic encephalopathy. Because most nutrients arrive through the portal vein, synthetic functions are also impaired, leading to hypoalbuminemia (contributing to ascites), decreased clotting factors (predisposing to bleeding), and reduced thrombolytic factors, such as antithrombin (predisposing to venous thrombosis).

Bleeding Esophageal Varices

The most life-threatening consequence of portosystemic shunting is the development of varices (enlarged and tortuous veins), which can occur throughout the GI tract but are most common in the esophagus and stomach. Bleeding from varices is one of the leading causes of morbidity and mortality in patients with cirrhosis. Varices are present at the time of diagnosis of cirrhosis in about 40% of patients and develop in an additional 6% per year.[105] In general, the risk of bleeding is low until portal vein pressure exceeds 12 mm Hg.[167] The major consequences of varices are rupture and bleeding, usually presenting as hematemesis.

The treatment of portal hypertension and varices is directed at either obliterating the dilated blood vessels or reducing portal pressure. Esophageal and gastric varices can be obliterated by either sclerotherapy or banding; this treatment is typically used for active bleeding or large varices. Sclerotherapy involves the injection by endoscope of a sclerosant (a chemical irritant) into the esophageal varices. Injections are performed weekly until all of the veins are obliterated. Banding is done endoscopically and involves placing rubber bands around dilated blood vessels. Meta-analysis of published studies shows higher efficacy for banding.[252] Occasionally, emergency portacaval shunt therapy is required but is associated with a rather high mortality rate. Esophageal tamponade may be obtained with a Sengstaken-Blakemore tube. This is a four-lumen tube with an esophageal and gastric balloon, and an aspiration tube that is placed in the stomach and in the esophagus above the esophageal balloon. Such balloons are fraught with hazard and are used only in extreme emergencies.

Portal pressure may be reduced pharmacologically. Numerous studies have shown that treatment with β-adrenergic receptor blockers is highly effective in reducing likelihood of bleeding from esophageal varices, and use of β-blockers is now considered the standard of care in individuals with portal hypertension, even if varices have not been documented.[105] As with all vascular epithelium, resistance is modulated by interaction between vasodilators, such as nitric oxide, and vasoconstrictors, such as endothelins. Unfortunately, there is evidence that changes in concentrations of such mediators are different between the liver and the peripheral circulation and, in many cases, exactly opposite. It is thus difficult to simultaneously improve hepatic blood flow and reduce peripheral vasodilation, and addition of nitrates to β-blockers has shown no advantage in lowering portal venous pressure.[166] The goal of treatment is to lower portal pressure below 12 mm Hg to reduce the likelihood of bleeding[140]; this not only lowers the risk of bleeding, but also lowers the likelihood of other complications of cirrhosis and improves survival.[5]

Drugs that specifically modulate portal pressure have yet to be developed. However, it has been shown that vasopressin, nitroglycerin, and octreotide will reduce portal pressure and are useful in acutely lowering portal venous pressure in individuals with active bleeding from varices. Vasopressin is given as a continuous intravenous infusion at 0.4 IU/min. The intense vasoconstriction may lead to myocardial and gastric infarction. Because of these side effects, it is given simultaneously with nitroglycerin, which greatly reduces the vasoconstriction. The success rate in stopping bleeding is about 60% to 70%, but mortality is not reduced. Octreotide works by different mechanisms but has a similar hemodynamic effect with fewer complications. It controls bleeding in 70% to 80% of patients. Pharmacological treatment can be combined with mechanical occlusion of varices by banding or ligation.

Various surgical procedures have been employed to reduce portal pressure. All involve increasing the shunting of blood around the liver to reduce portal pressure. In the past, shunts have been primarily surgical, such as connecting the portal vein to the inferior vena cava (portacaval shunt) or the splenic vein to the renal vein (splenorenal shunt). Currently, shunts are most commonly created by placing a stent through the jugular and hepatic veins to connect to the portal vein, called transjugular intrahepatic portosystemic shunt (TIPS).[269] Since portal flow is already significantly reduced before shunting, there is usually minimal change in liver function, but often reduction in likelihood of ascites and variceal bleeding. There is an increased incidence of hepatic encephalopathy following shunts.

Ascites

Ascites is the effusion and accumulation of fluid in the abdominal cavity. Ascites is the most common clinical finding in patients with portal hypertension. Ascites itself is not life threatening, but is uncomfortable and may compromise respiration (from upward displacement of the diaphragm and compression of the lungs). It also predisposes individuals to spontaneous bacterial peritonitis, which is life threatening.

The pathogenesis of ascites is complex because of a number of simultaneously operating factors. Of these, the most important are (1) increased hydrostatic portal venous pressure, with increased resistance to flow, (2) decreased colloid osmotic (oncotic) pressure because of hypoalbu-

minemia, and (3) leakage from the surface of the liver of protein-enriched fluid, which increases intraperitoneal colloid pressure. The primary event is probably peripheral vasodilation due to an imbalance of vasoactive factors, including endothelins. The net effect of these forces is to shrink the central blood volume, which decreases renal perfusion and leads to sodium retention through activation of the renin-angiotensin system. The sodium retention leads to water retention, but because of the increased portal hydrostatic pressure and decreased intravascular colloid pressure, the fluid leaks into the so-called third space, causing ascites and edema.

There are many causes of ascites, and it is important to differentiate ascites secondary to portal hypertension from ascites of other causes. This is done by analyzing ascitic fluid. The feature that best distinguishes portal hypertension is an increase in the plasma to ascitic fluid albumin gradient. A gradient greater than 1.1 g/dL is diagnostic of ascites caused by portal hypertension.[12]

Ascites is managed by creating a negative sodium balance or relieving portal hypertension. A negative sodium balance is obtained by reducing sodium intake or enhancing sodium excretion with the use of diuretics or both. Because most diuretics block proximal tubular reabsorption, more sodium is available at the distal renal tubule to exchange with potassium ion. Thus patients tend to become hypokalemic and require potassium preservation either with dietary supplementation or with potassium-sparing diuretics. Ascites may be safely removed with a catheter placed percutaneously through the abdominal wall. Five or 10 liters of fluid may be drained to relieve patient discomfort or respiratory compromise. Because ascitic fluid is nutritionally enriched, repeated fluid drainage leads to significant malnutrition. Repeated paracentesis also requires plasma volume expansion to prevent renal failure; albumin is effective as an expander.[310]

Spontaneous Bacterial Peritonitis

Ascites predisposes to spontaneous bacterial peritonitis, defined as bacteremia (typically gram negative) in the absence of mechanical disruption of the bowel.[96,287] It usually presents in an individual with known cirrhosis who develops abdominal pain, fever, or leukocytosis. The diagnosis is established by examination of the ascitic fluid; greater than 250 neutrophils per microliter, or more than 500 in the absence of a positive blood culture, is considered diagnostic.[52,301] In contrast, secondary peritonitis is usually associated with higher neutrophil counts, low glucose in ascitic fluid, and high protein.[13]

Hepatic (Portosystemic) Encephalopathy

Hepatic encephalopathy is a metabolic disorder characterized by a wide spectrum of neuropsychiatric dysfunction.[69] It may occur as an acute syndrome in patients with acute hepatic failure from viral or drug-induced hepatitis or as a chronic syndrome associated with liver failure and cirrhosis. As implied by the synonym, chronic hepatic encephalopathy occurs in the setting of portosystemic shunting, usually as a result of cirrhosis.

The clinical syndrome is variable but follows a reasonably predictable course. Disturbed consciousness always occurs. It usually starts as hypersomnia and progresses to sleep reversal in which the patient tends to sleep through the day and be awake at night. This is followed by decreased spontaneous movement, apathy, and gradually increasing levels of coma. Personality changes may be conspicuous, especially in patients with chronic disease. Irritability and disturbed social behavior may follow. Intellectual deterioration occurs (but is difficult to detect in its early stages because of confabulation) and generally progresses to overt confusion. Neurological abnormalities include slurred speech, a characteristic flapping tremor called asterixis, increased muscle tone, and abnormal reflexes. Disturbed gait may ensue. In chronic encephalopathy, these changes typically fluctuate over time and follow a waxing and waning course. Acute encephalopathy progresses rapidly, often within hours, and is characterized by cerebral edema, which may result in brain stem herniation and death.[94]

The pathophysiology of hepatic encephalopathy is not completely understood but includes an increased sensitivity to dietary proteins. Ammonia concentrations are always increased with acute encephalopathy and usually increased with chronic encephalopathy. A reduction of plasma ammonia is often associated with symptomatic improvement. However, since plasma ammonia concentrations do not correlate with the severity of the encephalopathy, it has been suggested that other factors are involved.[80,451] It is now recognized that a variety of neurotransmitter systems are dysfunctional in hepatic encephalopathy, but the exact cause for the changes is not known.[16] One important contributor is the endogenous benzodiazepine agonist system, but other abnormalities must be invoked to explain all the findings.[451]

The diagnosis of hepatic encephalopathy is made on clinical grounds. Plasma ammonia concentrations are rarely helpful, either for diagnosis or for monitoring the patient's disorder; normal ammonia concentrations are helpful in excluding hepatic encephalopathy as a cause of cerebral dysfunction. An exception is a patient who presents with acute encephalopathy of unknown cause. Elevated ammonia concentrations in that situation suggest acute hepatic failure or Reye's syndrome.

Treatment is largely empirical, based on observations that intestinal bacteria and protein loads in the intestinal tract are important in the symptoms of hepatic encephalopathy.[50] Lactulose has long been recognized to reduce the symptoms in chronic hepatic encephalopathy. Antibiotic treatment with a nonabsorbable antibiotic such as neomycin reduces the number of bacteria and is especially helpful in patients with GI bleeding. Protein reduction in the diet also improves encephalopathy; reducing dietary protein to the less than 40 g/day often needed to improve symptoms may compromise nutrition. Patients with acute encephalopathy require

measures to reduce intracranial pressure, such as osmotic diuretics.

Hepatorenal Syndrome

Hepatorenal syndrome (HRS) refers to decreased renal function secondary to hepatic disease; portal hypertension is a common factor in all cases of HRS developing in chronic liver disease, but HRS may also develop in acute liver failure. Although formerly thought to be a rapidly progressing, terminal event in a person with end-stage liver disease, it is now recognized that HRS falls into two major varieties.[31] Type 2 HRS is more common; it represents a slowly progressive or stable decline in renal function that is due to peripheral vasodilation and renal vasoconstriction. Type 1, or classic, HRS represents rapidly declining renal function, usually developing in a person with preexisting type 2 HRS. Type 1 HRS usually develops in the setting of an acute decrease in blood pressure, often due to spontaneous bacterial peritonitis or variceal bleeding.

The common feature in both forms of HRS is activation of the renin-angiotensin-aldosterone axis caused by intravascular volume depletion.[32] As with other forms of prerenal azotemia, HRS in the untreated patient is generally associated with increased antidiuretic hormone and with profound thirst. This leads to development of hyponatremia, hypokalemia, metabolic alkalosis, low urine sodium and high urine potassium excretion, and high urine osmolality. BUN, creatinine, and creatinine clearance are not reliable indicators of renal function in HRS.[31,116] Urea is produced by the liver and is often decreased in advanced liver disease; it is also increased after upper GI bleeding, a common cause for worsening of renal function in HRS. Creatinine production by muscle is reduced in cirrhosis, causing falsely low serum creatinine and creatinine clearance. Although cystatin-C has slightly better correlation with measured glomerular filtration rate (GFR), it is not clear that it reliably reflects renal function in cirrhotic individuals.

Treatment of HRS is best accomplished by either increasing systemic vascular resistance, as with the vasopressin analogue terlipressin, or reducing portal venous pressure, most commonly accomplished with TIPS. Both have shown promise in improving renal function in HRS.[17,247,471]

Altered Drug Metabolism

Because of the liver's central role in drug metabolism and disposition, alterations in drug metabolism may occur in patients with liver disease. In general, this is reflected in delayed metabolism such that the interval between drug doses has to be increased for drugs that are metabolized by the liver. Only patients with evidence of liver failure, such as encephalopathy, coagulopathy, or ascites, need alterations in dosing. In general, patients with liver disease are not more susceptible to drug-induced hepatotoxicity. However, patients with alcoholic liver disease who continue to consume alcohol are susceptible to liver injury from acetaminophen, even at therapeutic doses.[398]

Nutritional and Metabolic Abnormalities

The intake and disposition of nutrients in patients with chronic liver disease are altered, which subjects them to nutritional imbalance. Severe metabolic and nutritional derangements have been observed to occur in the cirrhotic patient including alterations in glucose metabolism caused by insulin resistance, and hypokalemia caused by secondary hyperaldosteronism in cirrhosis. In addition, hypoalbuminemia is frequently present because of decreased production and sinusoidal leakage of albumin in patients with portal hypertension. Also, in patients with chronic cholestasis, impaired delivery of bile salts to the duodenum results in malabsorption of lipids and fat soluble vitamins, leading to deficiencies in vitamins A, D, E, and K (see Chapters 30 and 49). Vitamin A deficiency may cause night blindness, but rarely progresses to serious visual impairment. Vitamin D deficiency causes osteopenia and, in severe cases, osteomalacia. In fact, osteopenic bone disease may be one of the most crippling results of chronic cholestatic liver disease, such as primary biliary cirrhosis.[192] Vitamin E deficiency is of little clinical significance. Vitamin K deficiency leads to hypoprothrombinemia, with easy bruising and bleeding.

Disordered Hemostasis in Liver Disease

The liver manufactures most of the clotting factors (the major exception being von Willebrand factor) and bile salts that are essential for absorption of vitamin K. The liver also clears activated clotting factors from the circulation. Thus chronic liver disease is associated with both a hemorrhagic tendency and a hypercoagulable state.[237]

The liver synthesizes fibrinogen factors V, VIII, XI, and XII, and the vitamin K–dependent factors II, VII, IX, and X. Furthermore the liver plays an important role in platelet growth and function. The vitamin K–dependent proteins contain γ-carboxy-glutamic acid. Vitamin K is necessary for the carboxylation of these proteins, which facilitate the conversion of prothrombin to thrombin. Patients with severe hepatocellular disease have decreased synthesis of the vitamin K–dependent clotting factors, especially factor VII. Furthermore, patients with cholestatic disease have decreased bile salt secretion, which is necessary for the absorption of vitamin K, leading to failure of activation of factors II, VII, IX, and X. In these patients, unlike those with hepatocellular disease, the prothrombin time can be corrected with an injection of vitamin K.

Disorders of fibrinogen also occur in the liver. For example, dysfibrinogenemia may be seen in both acute and chronic liver disease and leads to prolongation of the partial thromboplastin time.[158] Disseminated intravascular coagulation occurs with acute hepatic necrosis, presumably as a result of the release of tissue thromboplastin and defective clearance of inhibitors such as antithrombin and protein C. Thrombocytopenia may contribute to ineffective intravascular coagulation. Although commonly attributed to splenic sequestration (hypersplenism), there is evidence of antibody-mediated platelet destruction, as occurs in

immune thrombocytopenic purpura.[228] Patients with chronic or severe liver disease also may be hypercoagulable because of deficiency of liver-produced inhibitors of coagulation, such as antithrombin and proteins C and S. Patients with autoimmune hepatitis may have anticardiolipin antibodies and antibodies to platelets.

Enzymes Released from Diseased Liver Tissue

Because hepatic function is often normal in many patients with liver disease, the plasma activities of numerous cytosolic, mitochondrial, and membrane-associated enzymes are measured as they are increased in many forms of liver disease. As plasma enzyme measurements are discussed in greater detail in Chapter 21, only those factors relevant to understanding of liver disease will be summarized here.

Because the pattern and degree of elevation of enzyme activity vary with the type of liver disease, their measurement is extremely helpful in the recognition and differential diagnosis of liver damage. A number of factors govern the ability of liver enzymes to assist in diagnosis including their (1) tissue specificity, (2) subcellular distribution, (3) relative activity of enzyme activity in liver and plasma, (4) patterns of release, and (5) clearance from plasma.

Tissue Specificity

There are five enzymes that are commonly used in diagnosis of liver disease: Aspartate aminotransferase (AST; EC 2.6.1.1), alanine aminotransferase (ALT; EC 2.6.1.2), alkaline phosphatase (ALP; 3.1.3.1), and γ-glutamyl transferase (GGT; EC 2.3.2.2), are commonly used to detect liver injury, and lactate dehydrogenase (LD; EC 1.1.1.27) is occasionally used. ALT and GGT are present in several tissues, but plasma activities primarily reflect liver injury. AST is found in liver, muscle (cardiac and skeletal), and to a limited extent in red cells. LD has wide tissue distribution, and is thus relatively nonspecific. ALP is found in a number of tissues, but in normal individuals primarily reflects bone and liver sources. Thus based on tissue distribution, ALT and GGT would seem to be the most specific markers for liver injury.

Subcellular Distribution

Enzymes are found at different locations within cells. AST, ALT, and LD are cytosolic enzymes. As such, they can be released with cell injury, and appear in plasma relatively rapidly. In the case of AST and ALT, there are both mitochondrial and cytosolic isoenzymes in hepatocytes and other cells containing these enzymes. In the case of ALT, the relative amount of mitochondrial isoenzyme is small, and its plasma half-life is extremely short, making it of no diagnostic significance. In the case of AST, the mitochondrial isoenzyme represents a significant fraction of total AST within hepatocytes. In contrast, ALP and GGT are membrane-bound glycoprotein enzymes. The most important location of both enzymes is on the canalicular membrane of hepatocytes.

Relative Activity in Liver and Plasma

For cytoplasmic enzymes, the relative amount of enzyme in the liver relative to plasma is an important determinant of sensitivity. The activity of AST within hepatocytes is about twice that of ALT, although plasma activities are similar. In contrast, hepatocyte activities of LD are much lower (relative to plasma) than those of the other two enzymes, and plasma activities of LD are several times higher than those of AST and ALT. This means that there is less of an increase in LD with liver injury than occurs with AST and ALT. The relative amount of enzyme in tissue is not necessarily the same in disease; in cirrhosis and malnutrition, there are greater decreases in cytoplasmic ALT than in cytoplasmic AST.[272]

Mechanisms of Release

Several mechanisms appear to be involved in release of enzymes from hepatocytes. Cell injury is the simplest mechanism and appears to allow leakage of cytoplasmic enzymes from cells, but minimal release of other types of enzymes. Thus necroinflammatory disease leads to release of AST and ALT, and to a lesser extent LD, but not to mitochondrial isoenzyme of AST nor to release of ALP or GGT.[230] Alcohol appears to induce expression of mitochondrial AST on the surface of hepatocytes[492]; not surprisingly, alcoholic hepatitis is associated with increased plasma activities of this isoenzyme.[321,339]

The mechanism of release of membrane-bound enzymes such as GGT and ALP into the circulation is less well understood. There appears to be increased synthesis of GGT and ALP in diseased human liver.[313] How this enhanced synthesis of tissue-bound enzymes translates into increased activity in plasma is not clear. However, fragments of hepatocyte membrane rich in GGT and ALP activity have been detected in plasma of patients with cholestasis, a process that may be a result of membrane fragmentation by bile acids. Furthermore, bile acids, which are detergents, could solubilize and release GGT and ALP from plasma membranes. In vitro studies of membranes treated with bile acids demonstrate that this possibility exists.[391]

Rate of Clearance of Enzyme from Plasma

Clearance of liver enzymes from plasma occurs at variable rates. The half-life of ALT is 47 hours, of cytosolic AST, 17 hours; thus although more AST is released from liver, the much longer half-life of ALT leads to higher activities of ALT than AST in most forms of hepatocellular injury. The half-life of the liver isoenzyme of ALP has been variously reported as from 1 to 10 days; the former figure appears to correspond better to the changes seen with removal of gallstones. The half-life of GGT has been reported as 4.1 days. The mechanism by which enzymes are removed from circulation is not completely known, although receptor-mediated endocytosis by liver macrophages is likely involved.

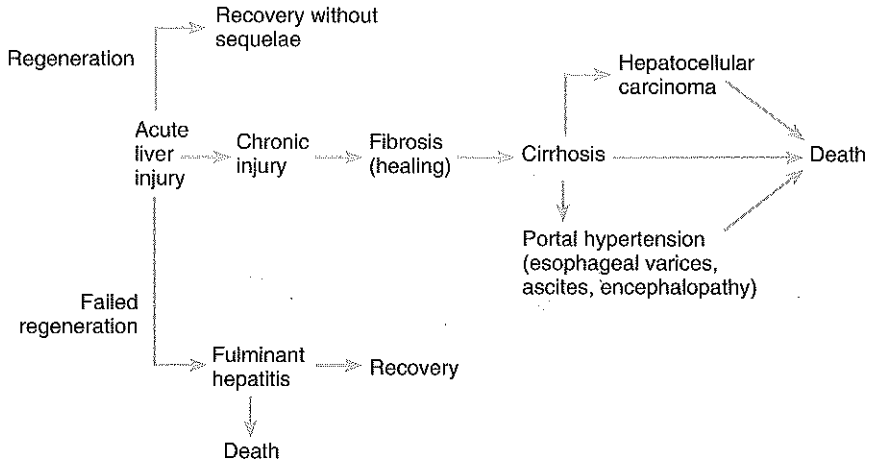

Figure 47-13 Natural history of liver disease.

DISEASES OF THE LIVER

The liver has a limited number of ways of responding to injury. Acute injury to the liver may be asymptomatic, but often presents as jaundice. The two major acute liver diseases are acute hepatitis and cholestasis. Chronic liver injury generally takes the clinical form of chronic hepatitis; its long-term complications include cirrhosis and HCC. The discussion of liver disease will focus mainly on these patterns, and a few diseases that differ from this general pattern. Because the types of disease seen in neonates differ significantly from this model, diseases of infancy are discussed separately in Chapter 31.

Mechanisms and Patterns of Injury

Cell death occurs by necrosis or apoptosis or both. The target cell determines the pattern of injury, with hepatocyte injury leading to hepatocellular disease and biliary cell injury leading to cholestasis. All cellular injury induces fibrosis as an adaptive or healing response, with the duration of injury and genetic factors determining whether cirrhosis and ultimately carcinoma occur (Figure 47-13).

Cellular necrosis occurs as the result of an injurious environment and has been referred to as "murder." It is characterized by cellular swelling with loss of membrane integrity. Toxic injury from compounds such as carbon tetrachloride, aspirin, and acetaminophen (Figure 47-14) occurs for the most part by necrosis. Apoptosis occurs as the result of accelerated programmed death in which the cell participates in its own demise and thus commits "suicide." It is characterized by cell shrinkage, with nuclear chromatin condensation and fragmentation forming apoptotic bodies. Regardless of the cause, cell death typically leads to leakage of cytoplasmic enzymes.

Laboratory tests are helpful in distinguishing the (1) pattern of injury (hepatocellular versus cholestatic), (2) chronicity of injury (acute versus chronic), and (3) severity of injury (mild versus severe). In general, the aminotransferase enzymes and ALP are used to distinguish the pattern,

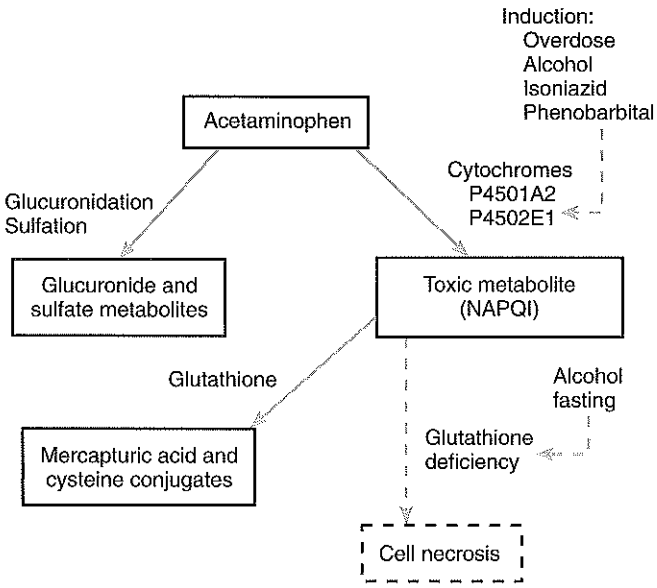

Figure 47-14 Metabolism of acetaminophen by the liver.

plasma albumin to determine the chronicity, and the PT or factor V concentration to determine the severity. At the present time, the only way to accurately detect fibrosis is by a liver biopsy.

Disorders of Bilirubin Metabolism

Defects in bilirubin metabolism resulting in jaundice are known to occur at each step in the metabolic pathway (see Figure 31-22, Chapter 31). Disorders related to these defects are discussed in Chapter 31 (see Box 31-1)

Hepatic Viral Infection

Five viruses have been identified (A, B, C, D, E) as causes of infection that primarily targets the liver. In addition, certain other viruses may infect the liver as part of a more generalized infection, among them cytomegalovirus (CMV), Epstein-Barr virus (EBV), and herpes simplex virus (HSV).

TABLE 47-2 Types of Viral Hepatitis

	A	B	C	D	E	G
Type	RNA	DNA	RNA	Partial	RNA	RNA

HAV, Hepatitis A virus; *HBsAg,* hepatitis B surface antigen; *PCR,* polymerase chain reaction; *IgM,* immunoglobulin M; *HCV,* hepatitis C virus; *HDV,* hepatitis D virus; *HEV,* hepatitis E virus; *HGV,* hepatitis G virus.
*Vaccination and passive immunization against HBV protects against HDV infection.

Several other viruses have been proposed as causes of liver injury; these include hepatitis G virus[1] (discussed below), transfusion-transmitted virus (TTV),[198] and the closely related SEN-V virus.[472] Although all three are blood borne chronic viral infections and, in the case of TTV and SEN-V, have been known to replicate in the liver, none of these viruses appear to cause acute or chronic liver injury.[332,445,481] The various hepatitis viruses are outlined in Table 47-2.

Hepatitis A Virus

Hepatitis A virus (HAV) accounts for about one fourth to one third the cases of clinical acute hepatitis in the United States and 20% to 25% worldwide. Although most commonly an infection of children and adolescents, the disease tends to be more virulent in middle-aged and older people. Most sporadic cases occur from person-to-person contact, such as occurs in children in day care centers. Epidemics have been associated with waterborne and food-borne contamination. Ingestion of raw shellfish from contaminated waters has caused both sporadic and epidemic cases. Although not as common a cause of liver infection as hepatitis B, it is more frequently associated with jaundice when occurring in adults than either hepatitis B or C; an estimated 50% to 70% of infected adults develop jaundice. In contrast, hepatitis A infection in children is rarely associated with jaundice, and thus is usually not detected clinically. The incidence of the disease is declining in the developed world with introduction of hepatitis A vaccine; complete immunization of less than half the at-risk population has been shown to reduce incidence of acute hepatitis A infection by more than 90% in areas of high endemicity.[34] Universal vaccination of infants in the United States is not currently recommended by the Centers for Disease Control and Prevention (CDC)[365]; immunization is recommended for children residing in areas with higher than average incidence of HAV, in individuals traveling to endemic areas, and in individuals who have chronic liver disease.

Hepatitis A is caused by a 27-nm RNA picornavirus. It has four capsid proteins (VP1-4), but only one serotype has been identified. The virus is not cytopathic to hepatoctyes, but causes liver injury by stimulating both cellular and humoral immune responses. Hepatitis A occurs in sporadic and epidemic forms, with an incubation period of 15 to 50 days. The clinical course of acute hepatitis A is usually that of a mild flulike illness that lasts for a few days to a few weeks. There is no chronic form of hepatitis A, but cholestasis (manifested by several weeks of jaundice and pruritus) may occur in some adults. Although a rare occurence, relapse in up to 5% of patients has been known to happen 1 to 3 months after the acute illness. It resembles the acute illness and is associated with viremia, but recovery always ensues.

Hepatitis B Virus

Hepatitis B virus (HBV) is the most common cause of acute hepatitis, and the most common chronic viral infection worldwide.[2] An estimated 350 million individuals are chronically infected with HBV, and several times as many individuals have been exposed to HBV. The frequency of chronic HBV infection varies worldwide. For example it is high in Asia and Africa but occurs rarely among those born in North America and Europe[135]; one study found that 86% of US residents with chronic HBV were actually born outside of the

United States.[241A] HBV is transmitted through body fluids, primarily by parenteral or sexual contact; it can be transmitted from mother to child, usually at or after delivery (termed vertical transmission). In parts of the world with high rates of chronic infection, much of the transmission is vertical. The residual risk from transfusion is estimated to be 1 in 600,000.[67]

Hepatitis B is caused by a 42-nm DNA virus that is a member of the hepadnavirus family. The DNA is partially double stranded, contains 3200 nucleotides, and has been cloned.[4] There are several major open reading frames. The S gene codes for HBsAg, a surface protein produced independently of and in excess of the amount needed for viral replication. The C gene encodes for HBcAg, part of the infectious core of the virus. The X gene codes for a transactivating factor that may be involved with viral replication and the development of malignancy. The precore region codes for production of the HBeAg, a protein found only in those with (but separate from) circulating viral particles. Hepadnaviruses are unusual among DNA viruses in that they reproduce from an RNA template using reverse transcriptase. Although DNA replication has a proofreading mechanism, reverse transcriptase does not; hepadnaviruses are thus prone to developing mutant strains. The significance of several mutants is described below.

Hepatitis B was first described in the 1960s by Blumberg and colleagues following discovery of a protein, termed the Australia antigen, that was initially felt to be a tumor marker for leukemia. Subsequent studies confirmed it to be a marker for a form of hepatitis initially termed serum hepatitis.[23] Later work establishrd that this was hepatitis B surface antigen (HBsAg). The complete HBV particle (Dane particle) of viral DNA consists of a core containing a number of proteins and envelope and surface proteins. The core, formed in infected cells, contains viral DNA, DNA polymerase, and core antigen (HBcAg). The surface protein (HBsAg) contains a common determinant, a, and four subdeterminants designated d, y, w, and r. The four major determinants are adw, adr, ayw, and ayr. Because the determinants breed true, they are helpful in epidemiological studies.[46] HBV species also have been classified into genotypes A-H; genotypes have less than 92% homology with other types. Although not routinely distinguished, there is evidence that genotype differences may have prognostic importance in chronic HBV infections. There are geographic differences in genotype distribution; genotype A predominates among those infected in North America, whereas genotype C is the dominant form in those infected in Asia. Genotype B is associated with a higher rate of spontaneous clearance in chronic infection,[484] slower progression of liver disease,[421] and better response to antiviral therapy[455] when compared with genotype C.

There are several mutants of HBV that may have clinical importance. The most common is due to one of a variety of mutations in the precore gene, most commonly a mutation at nucleotide 1896 that inserts a stop codon in the mRNA.[88] Mutations in the promoter region of the precore gene, particularly at nucleotides 1762 and 1764, are associated with reduced production of normal HBeAg. Such mutants are associated with undetectable HBeAg, although they are characterized by production of anti-HBe. Since HBeAg is often used as a marker of the presence of replicating virus, and anti-HBe with the absence of infectious virus, this limits utility of HBeAg testing. Precore mutants are found in the majority of individuals chronically infected with HBV in areas with high rates of infection, such as Asia and Southern Europe. In North America, it is estimated that 10% to 20% of individuals with chronic HBV infection have such precore mutants.[205] Such mutants may be present at the time of infection or may develop during the course of disease. Although initially it was thought that individuals infected with such mutants are much more likely to have severe acute infection, the high prevalence of such mutants suggests that this is not the case. Treatment with antiviral agents is equally effective in eradicating virus in the nonmutated and mutant strains. One of the most commonly used agents to treat HBV is the reverse transcriptase inhibitor lamivudine. As is true in HIV, there are specific mutations that confer resistance to antiretroviral agents. One common form involves mutations in the YMDD nucleotide binding region of the protease gene, in which substitution of isoleucine for methionine at amino acid 552 notably decreases lamivudine response.[18] Mutations can also affect other parts of the genome, and several strains with point mutations in HBsAg have also been identified. These mutants appear to be extremely rare; their major significance is that they may not be detected by immunoassays for HBsAg.[93] Rarely, infections by such mutants occur in individuals successfully immunized against HBV.[204] There is concern that such mutants may become more widespread, because their detection will be difficult and unexpected in those who have "protective" antibody titers from vaccination.[159]

Chronic infection with HBV occurs in two major forms. In the more severe form, chronic infection is associated with viral replication, reinfection of newly produced hepatocytes, and ongoing chronic inflammation (chronic hepatitis). Antiviral treatment is effective in suppressing viral replication in less than one third of such cases treated for one year; longer treatment with lamivudine increases response rate up to 60%-70%, but increases likelihood of development of resistant mutants. Individuals with ongoing viral replication have an estimated 30% risk of progression to cirrhosis over many years and have a sixtyfold increased risk of HCC (compared with those who are HBsAg negative).[477] In the less severe form, viral DNA becomes integrated into host DNA, and no viral replication occurs. Individuals with nonreplicating infection have minimal or no chronic inflammation and no risk of development of cirrhosis, but have a tenfold higher risk of development of HCC.[477]

Immunization. Hepatitis B may be prevented by either passive (hepatitis B immune globulin [HBIG]) or active

(hepatitis B recombinant vaccine) immunization. Initially, vaccination was targeted toward high-risk individuals, such as (1) babies of infected mothers, (2) individuals with promiscuous sexual practices, (3) health care workers, and (4) individuals having sexual contacts with infected individuals. In the United States, current data suggest that more than 90% of children have been immunized against HBV infection; most cases of HBV seen in the United States are now occurring in those born outside the United States or in their children. The incidence of acute HBV infection fell by more than 80% after initiation of immunization.[175,301A] Since infants born to HBsAg mothers have a high risk of developing chronic HBV infection, routine prenatal testing for HBsAg is needed to identify infants at risk. Infection occurs in only about 2% of infants before birth[428]; postexposure prophylaxis (typically used in infants of HBsAg positive mothers) consisting of passive immunization with 0.06 mL/kg of HBIG and the first dose of hepatitis B vaccine within 24 hours of birth is more than 95% effective in preventing infection.[114] A universal immunization program in Taiwan, where vertical transmission of HBV was endemic, greatly reduced the death rate from HCC in young individuals.[83]

Diagnostic Tests for Hepatitis B. Hepatitis B has the largest number of diagnostic tests of any of the hepatitis viruses, which makes for a more complicated interpretation of results. Testing currently involves primarily ELISA or related techniques to measure viral antigens or antibodies, but nucleic acid–based tests are becoming more widely used.

Hepatitis B surface antigen, the most widely used marker for detecting current hepatitis B infection, is detected by kits using antibody to HBsAg. Occasionally, false positive results occur in testing, particularly during pregnancy; a neutralization assay is available. Low level reactivity (as evaluated by the ratio of the signal from the sample to that of the cutoff for distinguishing positive and negative, termed the signal:cutoff [S/C] ratio) is highly predictive of samples that fail to confirm on neutralization.[336] False negative results can occur with mutants in the surface antigen; different assays differ in their ability to detect such mutants.[93]

Antibody to the hepatitis B core antigen (anti-HBc) is the most commonly detected antibody against HBV. Two assays are usually employed: IgM and total anti-HBc. IgM anti-HBc assays typically employ a large dilution of plasma (1:100) before analysis to reduce the likelihood of positivity in individuals with chronic HBV. The total antibody assay measures both IgM and IgG antibodies. Anti-HBc appears to last longer than anti-HBs in natural infection, and is still present in 97% of previously infected individuals more than 30 years after exposure. Isolated anti-HBc is a relatively common finding, particularly in the setting of HCV co-infection, but also in immunosuppressed individuals.[460] Although this may represent a false positive result, particularly as a transient phenomenon following influenza vaccination, current guidelines on hepatitis B recommend considering individuals with isolated anti-HBc to be considered hepatitis B immune.

Antibody to the hepatitis B surface antigen (anti-HBs) is considered evidence of immunity to hepatitis B and is the only marker found in those receiving the hepatitis B vaccine. The World Health Organization has developed a standard, defined as 10 IU/mL of anti-HBs. Current guidelines suggest that immunocompetent individuals who ever achieve an anti-HBs of 10 IU/mL or greater have life-long immunity to hepatitis B.

The hepatitis Be antigen (HBeAg) and antibody to the e antigen (anti-HBe) are typically used only in the setting of chronic HBV infection. Although HBeAg typically appears at about the same time as HBsAg in acute hepatitis, it is rarely used as a marker for acute infection. In chronic infection, HBeAg is used as a marker of persistence of infectious virus; its clearance and the appearance of anti-HBe have been used as indicators of conversion to the nonreplicating state and as goals of antiviral treatment. As discussed earlier, however, conversion may also occur with development of mutations in the precore region. Although presence of HBeAg is a specific marker for presence of replicating virus, the sensitivity of antigen detection for the presence of replicating virus is less than ideal. In parts of the world where precore mutants are common, patients with negative HBeAg and positive anti-HBe require further testing using HBV DNA to clarify the status of their infection. Such testing is becoming more common even in Europe and North America, where precore mutants are relatively rare.

Hepatitis B viral DNA is now often measured using an amplification technique (see Chapter 37). Until relatively recently, non-amplified assays were used that had relatively high limits of detection (compared with assays for HIV or HCV RNA or amplified HBV DNA assays). HBV DNA was typically reported in pg/mL; this amount of HBV DNA is equivalent to 285,000 copies/mL, with assays having lower detection limits of 0.5 pg/mL to 5 to 10 pg/mL. In 2001, the World Health Organization established an international standard for HBV DNA nucleic acid amplification techniques.[384] Currently, assays using amplification, particularly PCR methods, have detection limits in the range of 100 copies/mL, although non-amplified assays are still available. It is unclear what level of HBV DNA represents clinically important viremia, but two clinical practice guidelines have adopted 100,000 copies/mL as a "clinically significant" level of viremia.[267] In a large number of "carriers" of HBV, 97% had HBV DNA below 100,000 copies/mL,[282] and 89% of individuals who failed to clear the virus with antiviral treatment had HBV DNA above 100,000 copies/mL.[87] These data supports a value of 100,000 copies/mL as a good decision point for "significant" viremia. Alternatively the likelihood of response to treatment is low in those who do not have a complete suppression of HBV DNA to less than 100,000 copies/mL after 3 months of treatment.[68] As will be discussed later, however, the evolving concept of "occult" HBV infec-

tion may require use of much lower thresholds to define "significant" viremia.

Hepatitis B mutants are usually determined by direct sequencing. A line probe method has been developed for detecting the three most common mutants causing HBeAg negative chronic infection. YMDD mutants can be detected by a number of sequencing and hybridization assays. Genotype have been determined by various methods including direct sequencing, restriction fragment length polymorphism, line probe assay, or serotype.

Hepatitis C Virus

The hepatitis C virus (HCV) was the cause of the majority of cases previously known as non-A, non-B hepatitis. It was recognized in 1989[86] and fully characterized 2 years later.[203] It is the most common cause of chronic hepatitis in North America, Europe, and Japan; it is estimated to infect approximately 170 million individuals worldwide. Although HBV infection appears to have been present for a long time, there is evidence that HCV is a more recently developing viral infection, because rates of HCV-related liver disease have been increasing in many parts of the world. Predictions are that HCV-related end stage chronic liver disease will increase twofold to threefold over the next 20 to 30 years.[109] HCV infection primarily occurs through plasma; the major risk factors are injection drug use and transfusion. For example, before the recognition of and availability of tests for HCV, the frequency of post-transfusion hepatitis (mainly due to HCV) was 3.5%[395A]; the risk of HCV transmission by transfusion was estimated at 1:2,000,000.[67] Because of its mode of spread, HCV infection is rare in children; the only common causes of pediatric infection are vertical transmission from an infected mother (estimated to occur in about 5% of infected women)[373] and, previously, transfusion of infected blood.

HCV is a single-stranded enveloped RNA virus of the flavivirus family, which includes other hepatitis viruses (yellow fever virus) and viruses that cause unrelated disease (such as West Nile virus). HCV RNA contains one reading frame (Figure 47-15). The resulting polypeptide is cleaved to core and envelope antigens and a number of nonstructural (NS) proteins, including a polymerase, a protease, and an interferon-response element. As an RNA virus, HCV is subject to a high rate of spontaneous mutation, giving rise to large numbers of variants. This results in six major genotypes (<70% nucleotide homology), along with a number of subtypes (77% to 80% homology).[62] In a chronically infected individual, there are numerous quasispecies (>90% homology) that develop over time. These quasispecies seem to be important in establishing chronic infection[143] and appear related to the fluctuating nature of chronic inflammation in chronic HCV infection.[142] Quasispecies are unique to the individual infected; those infected from a common source show different patterns of mutation.[263]

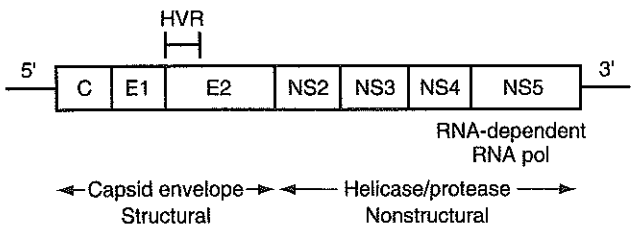

Figure 47-15 Structure of hepatitis C genome.

Chronic HCV infection is associated with evidence of chronic liver injury in most cases. Elevations in liver-associated enzymes, particularly ALT, are usually mild and fluctuate between normal and abnormal in most infected individuals. In an estimated 15% to 20% of cases, cirrhosis becomes evident an average of 20 to 30 years after exposure. HCC may develop once cirrhosis is present at an average rate of 1.5 to 3 cases per year. In North America, Europe, and Japan, HCV is the most common risk factor in development of HCC. There are a number of extrahepatic manifestations of chronic HCV infection; the most common are cryoglobulinemia and porphyria cutanea tarda. There is epidemiological evidence linking HCV to increased risk of lymphoma and type 2 diabetes mellitus.

Prevention. Prevention of hepatitis C has proven to be more difficult than with HAV and HBV. However, there has been an 80% decrease in incidence of acute HCV over the past decade, which is thought to be due to testing blood donors for HCV and to safe injection practices instituted to reduce risk of HIV infection. Vaccine development has been difficult because of the many subspecies of virus and the presence of many quasispecies with different antigenic determinants. There have been significant improvements in treatment of HCV infection, however. Treatment of acute hepatitis C with α-interferon monotherapy has been found effective in preventing chronic hepatitis in a large majority of patients in nonrandomized trials. The use of pegylated interferon and ribavirin combination therapy leads to viral eradication in about 75% of those infected with genotypes 2, 3 and 4, and almost half of those infected with genotype 1.

Diagnostic Tests for Hepatitis C. Antibody to HCV (anti-HCV) is the principal screening test for HCV exposure. The tests, using ELISA and related microparticle, chemiluminescence formats, detect the presence of antibodies to one or more HCV antigens (derived by recombinant technology from yeast cultures or through production of synthetic peptides). Although the initial assay detected only antibody to a single antigen, subsequent tests have used antigens from four different regions of the HCV genome. Second generation assays become positive an average of 12 weeks after exposure, while third generation assays become positive an average of 9 weeks after exposure. After comparison with a cutoff value, results are interpreted as positive or negative. As is true for HBsAg, samples with low S/C ratio are often false positive, whereas false positive results are rare in samples with high S/C ratio.[128,129] Current CDC recommen-

dations suggest using an S/C ratio of <3.8 for both second and third generation ELISA assays, and an S/C ratio of <8.0 for the chemiluminescence assay, to define low positive results.[20] Samples with low S/C ratio are recommended to be confirmed, ideally using recombinant immunoblot assay (RIBA).

RIBA is a technique similar in principle to Western blot (see Chapter 5). The HCV antigens used in the anti-HCV assays are typically blotted onto a membrane as dots, and reactivity is detected after incubation with serum. Results are interpreted as negative if there is less than 1+ reactivity with any of the four antigens, indeterminate if there is 1+ or greater reactivity to only a single antigen (or to more than 1 antigen along with the nonspecific yeast marker superoxide dismutase), and positive with 1+ or greater reactivity to multiple antigens. Third generation RIBA has considerably fewer indeterminate results than second generation RIBA.

HCV RNA measurement has become the most widely used test to detect current HCV infection. Typical of RNA in general, HCV RNA is labile in whole blood, because of the action of RNAses primarily found in red blood cells. Rapid separation of serum from clot is critical for accurate measurement of HCV RNA. If serum is separated from the clot by centrifugation within 1 hour, HCV RNA does not show an appreciable decline until 6 hours after collection. If serum is physically separated from cells within 1 hour, samples are stable at room temperature for 3 days, at refrigerator temperatures for a week, and indefinitely if frozen.[111] Samples collected in EDTA, which inhibits enzyme activity, are stable for 24 hours even if plasma is not separated from red cells.[180]

Assays for HCV RNA are generally divided into qualitative and quantitative variants. An international standard for quantification of HCV RNA has been developed,[385] and quantitative HCV RNA assay results are calibrated using this standard and reported in international units per milliliter (IU/mL). The relationship between IU/mL and copies/mL differs significantly for different assays. Results expressed in IU/mL agree within 1 log in about 90% of samples, but discrepant results do occur.[405] Until recently, qualitative assays had significantly lower detection limits than quantitative assays, but some newer quantitative assays have equivalent or lower detection limits compared with qualitative assays; it is likely that qualitative assays will become obsolete as sensitive quantitative assays become commercially available. Currently the most sensitive qualitative assay involves transcription-mediated amplification (TMA); its detection limit is 5 IU/mL. A commercially available qualitative reverse transcriptase/polymerase chain reaction (rt-PCR) assay has a detection limit of 50 IU/mL. Two quantitative assays are commercially available: an rt-PCR assay with a measurement range of 500 to 500,000 IU/mL and a branched DNA (bDNA) assay with a dynamic range of 615 to 8 million IU/mL. Several other assays, available as analyte-specific reagents or offered only by reference laboratories, have lower detection limits similar to those of qualitative assays and upper detection limits similar to or higher than those of the bDNA assay.

Hepatitis C core antigen (HCV Ag) is produced by the most constant part of the HCV genome. HCV Ag is one of the major targets of antibody formation, and most HCV Ag circulates bound to antibody. HCV Ag has a similar time course to that of HCV RNA in both acute and chronic HCV infection[426]; the currently available assay for HCV Ag becomes reliably positive when HCV RNA is 20,000 IU/mL or greater.[58] In our experience with several thousand HCV RNA samples, less than 5% of untreated HCV RNA positive individuals have a viral load <20,000 IU/mL. In contrast to HCV RNA, HCV Ag is stable on storage.[427]

Hepatitis C genotype is an important parameter in determining length and intensity of antiviral therapy. Several methods are currently used to determine the infecting genotype. Although serological assays to detect antibody to specific genotypes of HCV are available, their correlation with more definitive tests is approximately 90%,[351] and a significant minority of infected individuals have antibodies to more than one genotype.[434] However, detection of viral RNA of more than one genotype is exceptionally rare. The most reliable method involves direct sequencing of regions of the genome that show characteristic patterns with specific genotypes and subtypes. Commercial assays using the 5′-untranslated region are most widely used,[377] although assays using the NS5b region are now available. A commercial line probe assay is the most widely used technique, since it is relatively simple to perform and interpret. Sequences from specific strains of HCV are immobilized on a membrane, and the pattern of banding following hybridization and addition of indicator is interpreted. The technique cannot distinguish some of the less common genotypes and occasionally has patterns that do not correspond to a specific genotype. Overall agreement with direct sequencing methods is high.[305]

Hepatitis B and C Co-infection

Approximately 2% to 10% of individuals infected with HCV are co-infected with HBV; of those with chronic HBV, 15% to 20% are also HCV positive.[99,490] The clinical and laboratory features of co-infected patients are somewhat contradictory, and differ from those in individuals infected with a single hepatitis virus. Co-infected patients have lower viral loads than do those with single infection.[98] In patients with chronic HBV who develop acute HCV infection, the likelihood of progressing to chronic HCV infection is lower.[89] These features would suggest a beneficial effect of co-infection. In contrast, patients with chronic HBV/HCV co-infection have more rapid progression to cirrhosis.[382] Patients with acute co-infection more frequently have severe acute hepatitis.[15,490] Some studies suggest that there is a high frequency of HBV DNA viral replication in the liver even in the absence of circulating HBsAg; such subclinically co-infected patients have more severe liver injury and a higher frequency of cirrhosis.[71,243] Despite some favorable findings, the outcome of

hepatitis in co-infected patients seems to be worse than for those infected with only a single agent.

Hepatitis D Virus (Delta Agent)

Hepatitis D virus (HDV) is an incomplete, 36-nm RNA particle that cannot replicate on its own.[411] It is coated with HBsAg and is dependent on HBV for its activation. It is thus a satellite virus similar to that seen in plants. The D virus is a single-stranded antisense RNA virus. It is very infectious and strongly associated with intravenous drug abuse; approximately 10 million persons have been infected worldwide,[185] although the incidence is declining with the fall in incidence of HBV infection.[231] It occurs as simultaneous infection with hepatitis B (co-infection) or as superimposed infection in someone with chronic hepatitis B (superinfection). Co-infection usually runs the same time course as acute hepatitis B and HDV is spontaneously cleared as the hepatitis B resolves, but the risk of fulminant hepatitis is higher than in HBV infection alone, and mortality is higher. Superinfection typically results in chronic HDV infection, suppression of HBV DNA replication, and more rapid progression to cirrhosis. It should be suspected in a chronically infected HBV patient whose condition worsens.[476] Although traditionally diagnosed serologically by detection of anti-HDV (total or IgM) and/or HDVAg,[323] currently HDV RNA measurements are often used as evidence of current infection.[307]

Hepatitis E Virus

Hepatitis E virus (HEV) is a 34-nm, single-stranded, unenveloped RNA virus. It accounts for sporadic and epidemic hepatitis in tropical and semitropical countries and in people returning from these areas.[474] Although considered to be rare in Europe and nontropical areas of North America, it was identified in 1999 as a cause of hepatitis in the United States,[139] and HEV RNA is frequently isolated from city sewage treatment plants in such nonendemic areas.[91] It is enterically transmitted, as is HAV, and viral RNA has been detected in stool.[443] There is probably only one species. Tests to detect antibody to HEV have been developed; specificity for HEV is high only for assays detecting antibody to the open reading frame 2 (ORF2) antigen.[283] The prevalence of antibodies to HEV is high among those living in urban areas and in blood donors,[432] and HEV has been isolated from rats[227] and pigs[297]; the significance of this is unclear, although it has been speculated that HEV is a zoonotic disease.[296] The clinical course is similar to that of HAV infection in that HEV typically infects young people, has a self-limited course, and is not associated with chronicity. A peculiar feature of this disease is its virulent course in late pregnancy, with mortality generally in the range of 20% to 25%, but rates as high as 50% have been reported.[241]

Hepatitis G Virus

Hepatitis G virus (HGV), also known as GBV-C, is an RNA virus of the flavivirus family, closely related to HCV.[4] It has been found to be transmitted by the same means as HCV, although most commonly it is transmitted by plasma[220]; vertical transmission has been reported.[306] Although it has a very high infectivity rate in recipients of contaminated blood (>90%), there seem to be no adverse consequences to HGV infection.[461] In fact, although it has been called a hepatitis virus, viral RNA cannot be isolated from the liver in chronic infection.[253] Co-infection with HCV and HGV is common, but there is no effect of co-infection on prognosis in HCV.[342,479] HGV and HIV co-infection is also common[473]; individuals co-infected with HGV and HIV have lower HIV viral loads and a better prognosis than those infected with HIV alone.[258,433,435]

Acute Hepatitis

Acute hepatitis refers to an acute injury directed against the hepatocytes. The injury may be mediated either directly—as occurs with certain drugs, such as acetaminophen, or with ischemia—or indirectly, as occurs with immunologically mediated injury from most of the hepatitis viruses and most drugs, including ethanol. In direct injury, there is typically a rapid rise in cytosolic enzymes, such as AST, ALT, and LD, followed by a rapid fall with rates of decline similar to known half-lives of the enzymes. With immunological injury, there is a gradual rise in cytosolic enzymes, a plateau phase, and a gradual resolution of enzyme elevation. Although jaundice is a key clinical finding in acute hepatitis, it is often absent (as discussed below under the various forms of viral infection). An increase of AST activity to greater than 200 IU/L, or of ALT activity to greater than 300 IU/L, has sensitivity and specificity of greater than 90% for acute hepatitis.[380] ALP is usually mildly elevated, and is less than three times the upper reference limit in 90% of cases of acute hepatitis.[380] Bilirubin elevation, when present, typically is predominantly direct reacting bilirubin; indirect bilirubin is higher than direct bilirubin in about 15% of cases.[55] The distribution of direct bilirubin percentage is identical in acute hepatitis and bile duct obstruction, making direct bilirubin inconsequential in the differential diagnosis of jaundice.[55] Liver synthetic function is usually well preserved in most forms of acute hepatitis. These and other features that are helpful in the differential diagnosis of acute hepatitis are summarized in Table 47-3.

The outcome of acute hepatitis is variable. In most cases, complete recovery occurs and liver regeneration leads to normal structure and function. With some viruses, failure to clear infection leads to development of chronic hepatitis. In a small percentage of cases, massive destruction of the liver leads to acute (fulminant) hepatic failure, which is associated with high mortality unless liver transplantation can occur.

Acute Viral Hepatitis

All forms of acute viral hepatitis have similar pathology and a similar clinical course. They are all diagnosed on the basis of marked elevations in aminotransferases, usually between 8 and 50 times the upper reference limits, with only slight

TABLE 47-3 Laboratory Features of Different Forms of Acute Hepatitis

Type	AST/ALT	ALP	Bilirubin	PT	Serology	Other
Viral	8-50 × URL	<3 URL	5-15 mg/dL	<15 s	Positive	
HAV					IgM anti-HAV	
HBV					HBsAg, IgM anti-HBc	
HCV					HCV RNA, ±anti-HCV	
Alcoholic	<8 × URL	>3 × URL in 25%	5-15 mg/dL	<15 s	Negative	AST > ALT
Toxic	>50 × URL	Normal	<5 mg/dL	>15 s	Negative	Toxin usually detectable; acute renal failure common
Ischemic	>50 × URL	Normal	<5 mg/dL	>15 s	Negative	Acute renal failure common
Drug induced	8-50 × URL	>3 × URL in 50%	5-15 mg/dL	<15 s	Negative	Eosinophilia, skin rash common
Autoimmune	8-50 × URL	<3 × URL	5-15 mg/dL	<15 s	Positive ANA or ASMA	Low albumin, high globulins
Wilson	8-50 × URL	Low normal or decreased	5-15 mg/dL	<15 s	Negative	Hemolytic anemia, renal failure common; low ceruloplasmin often absent

URL, Upper reference limit.

elevations in ALP and little or no effect on hepatic synthetic function. ALT is typically higher than AST because of slower clearance. Enzyme elevations typically peak before peak bilirubin occurs, and remain increased for an average of 4 to 5 weeks (longer for ALT than AST because of its longer half-life). Bilirubin elevation is variable, as discussed below. The incidence of acute viral hepatitis has declined notably since the late 1980s, with the decline reaching less than 20% of previous concentrations for both HBV and HCV by the late 1990s.[29,175,241A] The decline in incidence of these viruses seems to be caused by widespread immunization for HBV, along with reduction in risk of infection by injection drug use (thought to be related to safer injection practices following discovery of the human immunodeficiency virus) and safe sex practices. There has not been a similar decline in the overall incidence of HAV.[30] The lack of universal vaccination programs for HAV seems to explain the continued high incidence, since immunization of about half of susceptible individuals was associated with a 92% decline in incidence of HAV in one high-risk area.[34]

Acute Hepatitis A

In adults, about 70% of those with acute HAV infection develop jaundice much more commonly than with HBV or HCV. In children, acute HAV infection typically goes unrecognized and is often considered to be a viral gastroenteritis or other viral disease, since only 10% of children become jaundiced. The disease is more prolonged and serious in individuals over age 50. The specific etiological diagnosis is made with serological tests. An IgM antibody (anti-HAV IgM) appears early in the course of illness and persists for an average of 2 to 6 months; rarely, IgM antibodies may remain positive for a year or longer. The presence of IgM anti-HAV is therefore considered diagnostic of recent HAV infection. An IgG antibody (anti-HAV IgG) appears shortly after IgM antibody, and persists for many years (probably for life), inducing lifelong immunity. Total anti-HAV antibody assays detect both IgM and IgG anti-HAV. Both IgM and, subsequently, IgG anti-HAV also develop following immunization with the hepatitis A vaccine. There are no antigen tests for detection of hepatitis A in plasma. Incubation of stool samples with labeled antibodies to hepatitis A and examination with an electron microscope have been used to detect infectious viral particles in the past. Amplification techniques (usually using rt-PCR) have been used to detect virus in epidemiologic studies, but are not routinely used to diagnose infection.

Acute Hepatitis B

In most of the world, HBV is the most common cause of acute viral hepatitis. As with HAV, most infections in children are clinically silent. An estimated 30% to 50% of adolescents and adults with acute HBV infection develop jaundice. The outcome in acute HBV infection is strongly influenced by age and immune status. In healthy adolescents and adults, an estimated 1% to 3% of cases will progress to chronic infection. In a person with immunosuppression, the likelihood of chronic infection increases to 10%. Neonates infected with HBV have a 90% likelihood of chronic infection, and the risk falls gradually over the first 5 years of life.

The serological course of acute hepatitis B infection is illustrated in Figure 47-16. HBsAg is the first serological

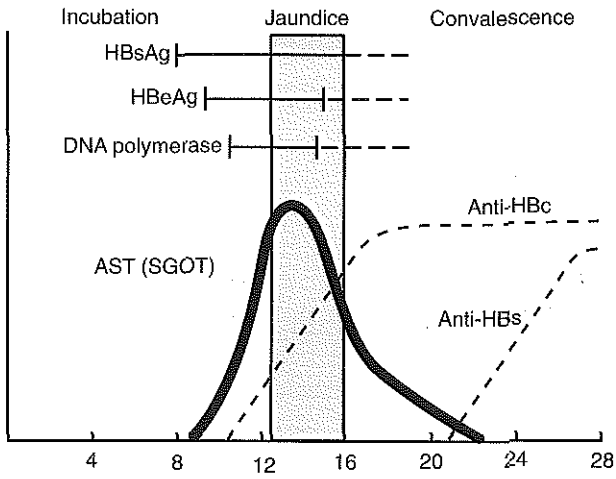

Figure 47-16 Course of acute type B hepatitis with recovery. *1*, Onset of hepatitis with jaundice 3 months after exposure; 2, detection of hepatitis B surface antigen (HBsAg) 2 to 8 weeks after exposure, followed by appearance of its antibody (anti-HBs) 2 to 4 weeks after HBsAg is no longer detectable; 3, detection of hepatitis Be antigen (HBeAg) shortly after appearance of HBsAg disappears (this is usually followed by the appearance of antibody to HbeAg [anti-Hbe], which persists); 4, detection of hepatitis B core antibody (anti-HBc) at the time of onset of disease 2 to 3 months after exposure. Anti-HBc IgM will be detectable in high levels for ~5 months. *(From Balistreri WF. Viral hepatitis: Unique aspects of infection during childhood. Consultant 1984; 24:131-53.)*

marker to appear, although HBV DNA may be detectable slightly earlier. HBsAg usually appears 1 to 2 months after infection and before the onset of clinical illness, and is the last protein marker to disappear. HBV DNA replication is slower than that of HCV; doubling time averages 2 to 3 days.[462] Persistence of HBsAg for more than 6 months beyond the onset of acute hepatitis indicates chronic infection. HBeAg appears at about the same time as HBsAg; however, because it is not usually measured except in the setting of chronic HBV infection, it is usually not helpful as a marker to document acute infection. The first antibody to appear, usually coinciding with the onset of clinical evidence of hepatitis 3 to 6 months after infection, is antibody to the hepatitis B core antigen (anti-HBc). As with hepatitis A, an IgM antibody is the first to appear, and usually persists for 3 to 6 months; it is usually considered diagnostic of acute hepatitis B infection. In chronic infection, however, IgM antibody may become detectable with flares of severity of disease and is thus not completely reliable in recognizing a recent infection. The typical pattern at clinical presentation is positive serology for anti-HBc (both total and IgM), HBsAg, HBeAg (when measured), and negative anti-HBs. A small percentage of individuals have negative HBsAg and anti-HBs at the time of initial presentation, leaving IgM anti-HBc as the only commonly measured marker to be positive; this finding has been termed the "core window." With current, sensitive assays for HBsAg, it is rare to encounter individuals in the core window. Clearance of HBeAg and development of anti-HBe is the first sign of viral clearance and usually predates loss of HBsAg. Clinically, HBsAg clearance is associated with recovery from acute hepatitis and has been thought to confer lifelong immunity to HBV.

More recently, accumulating evidence indicates that HBV remains dormant in the body and HBV DNA circulates in many to most individuals who have "recovered" from acute hepatitis. This has been termed "occult" HBV infection. At the time of publication, the significance of such occult infection is unclear, as reviewed by Brechot.[59A] Several studies have demonstrated that HBV DNA is still present in low amounts, both in the plasma and liver, in most individuals who had past acute HBV infection and who were HBsAg negative and anti-HBs positive.[460,485] Viral loads are typically 100 copies/mL or lower, and it has been estimated that the number of liver cells infected may be as low as 1%. Such individuals have been shown to transmit HBV infection if their organs are used for transplantation. The significance of circulating HBV DNA to the individual infected or to others (in the absence of transplantation) seems to be minimal, however, since liver enzymes are usually normal and the circulating HBV DNA is mainly found in immune complexes.

Acute Hepatitis C

Acute HCV infection is responsible for 10% to 15% of cases of acute hepatitis in the United States; an estimated 10% to 30% of those with acute infection develop jaundice. Increased aminotransferases usually develop about 6 to 8 weeks after infection. In those cases in which clinical acute hepatitis develops, jaundice typically begins about 2 to 3 months after exposure. HCV RNA and HCV core antigen are detectable in plasma 2 to 4 weeks after initial exposure. Viremia increases rapidly (average doubling time of 17 hours), and plateaus at high viral loads (often > 10^7 IU/mL). In acute hepatitis C infection, anti-HCV is present in a little more than half of cases at the time of presentation.[39,182] IgM anti-HCV assays are not commercially available, but in contrast to HAV and HBV, IgM antibodies are encountered in both acute and chronic HCV infection, making the test useless diagnostically.[330] HCV RNA and HCV core antigen are usually both present at the time of diagnosis and viral load is often significantly elevated compared with values seen in chronic hepatitis. Diagnosis of acute HCV is likely if anti-HCV is absent but HCV RNA or core antigen is positive. Diagnosis of acute HCV is also likely if HCV RNA viral load is high and anti-HCV titer is low, or increases with time.[330,343] Viral load falls with development of antibody to one or more HCV proteins, and may become transiently negative.

Other Types of Acute Viral Hepatitis

A number of other viruses can affect the liver, causing acute hepatitis. The most common are the Epstein-Barr virus and cytomegalovirus. Features are otherwise typical of

viral hepatitis, although there are often signs of systemic infection as well. Herpes simplex virus may occasionally cause severe hepatitis in adults.[235] Infection with each of these agents is more commonly associated with hepatitis in the neonatal period, where it is part of disseminated infection. Diagnosis of infection with these viruses involves serological and nucleic acid tests; none of them are specific to the liver.

Sudden outbursts of activity in individuals with chronic hepatitis B may mimic acute hepatitis. There are common situations in which an acute rise in cytoplasmic enzymes occurs, often associated with jaundice and other clinical features suggesting an acute liver disease. For example, development of an immune response that leads to clearance of either HBeAg or HBsAg is often associated with clinical and enzymatic features of acute hepatitis.[110] Recognition of this cause of the clinical picture of acute hepatitis in a person with chronic hepatitis relies on demonstration of antigen loss and antibody development, along with absence of other causes of acute hepatitis. Withdrawal of agents that suppress either the immune response (especially corticosteroids) or viral replication (particularly lamivudine),[353] or restoration of the immune system (by treatment of HIV infection)[379] has been associated with a clinical picture that mimics acute hepatitis; fulminant hepatic failure and death have been associated with these events. Diagnosis is usually dependent on clinical history.

Toxic Hepatitis

Toxic hepatitis refers to direct damage of hepatocytes by a toxin or toxic metabolite. Toxic reactions are usually predictable, and are directly related to the dose of the agent ingested. In North America and Europe, the most common cause of toxic hepatitis is acetaminophen, a widely used nonprescription pain reliever.[47] The metabolism of acetaminophen is affected by dose, induction of metabolic enzymes, and concentrations of glutathione (Figure 47-14). When a large dose of acetaminophen is ingested (average lethal dose 15 g), the metabolic pathways are overwhelmed, glutathione is depleted, and toxic intermediates accumulate and cause liver damage. When metabolic enzymes are induced (such as by ethanol) or glutathione is depleted (as occurs in alcoholics and with starvation), toxicity can occur with relatively small doses of acetaminophen (total doses of 2 to 4 g). The first laboratory abnormality to appear is an increase in PT, followed by increased activities of cytosolic enzymes. Initially, LD is often increased to higher absolute amounts than AST, and AST tends to be higher than ALT.[74] Peak activities (typically more than 100 times the upper reference limits) usually occur by 24 to 48 hours, followed by rapid clearance at rates approximating the known half-lives of the enzymes.[410] PT elevations are typical and are greater than 4 seconds above the control value in most cases.[337] Prognosis is related most closely to the prolonged increase in PT; persistent elevation of PT 4 days after ingestion is associated with a poor prognosis.[189] Other markers of risk include development of acute renal failure and presence of lactic acidosis, particularly if pH is <7.30.

Ischemic Hepatitis ("Shock Liver")

Hepatic hypoperfusion (ischemic hepatitis) is one of the most common causes of elevated cytosolic enzymes; in hospital patients, it is the cause of the majority of cases of acute hepatitis.[197,463] Ischemic hepatitis follows any cause of shock; the most common causes are septic and cardiogenic shock (sometimes termed cardiac hepatopathy).[317] Bilirubin elevations typically are minimal, and usually peak several days after enzyme activity reaches its greatest point.[130] Laboratory findings are similar to those in toxic hepatitis (including having high LD), and acute renal failure is a common complicating factor. Prognosis is primarily related to the underlying cause of hypotension[130]; individuals with prolonged elevation of bilirubin appear to have a poor prognosis.[38]

Reye's Syndrome

Acute encephalopathy in combination with fatty degeneration of the viscera was initially described by Reye and associates in Australia in 1963,[370] with nearly simultaneous case descriptions by Johnson and colleagues in the United States.[222] In the majority of these early cases, the disease was fatal. It most frequently strikes children aged 6 to 11 years and infants, although it may affect other ages. The syndrome is characterized by a prodromal, febrile viral illness (usually influenza B or varicella), followed in about a week by protracted vomiting associated with lethargy and confusion,[261] which may deteriorate rapidly into stupor and coma. At the same time, the liver enlarges, increased aminotransferases and PT develop, and ammonia increases. A PT prolonged greater than 3 seconds above normal and a plasma ammonia level greater than 100 μmol/L usually indicate a poor prognosis. Bilirubin is typically normal or only mildly increased. Other laboratory features include hypoglycemia and hyperuricemia.

Only sporadic case descriptions of Reye's syndrome were published until 1974, when 379 cases in the United States were reported to the CDC. The mortality rate in this series was 41%. The number of cases peaked in 1980 at 555.[43] At about the same time, articles began to appear linking Reye's syndrome with aspirin treatment of viral illnesses,[409] followed by a case control study strongly implicating salicylate in the pathogenesis of Reye's syndrome.[188] Although CDC guidelines recommending avoidance of aspirin in children with febrile illnesses were not published until 1985,[206] a decline in salicylate use began before this, and Reye's syndrome has again become a rare disease.

Other Causes of Acute Hepatitis

Drugs can cause liver injury by a number of mechanisms, but the most common is idiosyncratic, immune-mediated injury to hepatocytes,[265,494] characterized by elevations in

ALT or AST.[22] Cholestatic hepatitis, with increased aminotransferases and ALP, is more common in drug-induced hepatitis than with other causes of acute hepatitis. Criteria to recognize drug-induced liver disease include temporal relationship between drug exposure and onset of hepatitis; exclusion of other known causes of hepatitis; presence of extrahepatic hypersensitivity (especially skin rash, arthralgia, renal injury, and eosinophilia); development of liver injury on rechallenge; and, ideally, previously published reports of similar reactions.[279] Several standardized approaches to evaluation of possible drug-induced liver disease have been developed.[106,415] Hepatic drug reactions represent about 6% of all adverse drug reactions,[125] and about 1% of cases of acute hepatitis.[249] Although usually associated with prescription drugs, complementary and alternative products are becoming increasingly recognized as causes of acute hepatitis.[85,420] Although drug reactions typically develop soon after start of treatment, several months may elapse between initial exposure and development of acute hepatitis. Approximately 60% of cases cause severe acute hepatitis with jaundice, and fatalities can occur.[95] Serious reactions are more common in individuals who are continued on the medication.[348] In about one third of cases, liver injury becomes chronic following cessation of the drug.[22]

Some disorders that usually produce chronic hepatitis (and are discussed more fully below) may occasionally present in an acute fashion. Autoimmune hepatitis has an acute component in up to 40% of cases. Clinically, it differs from other forms of acute hepatitis in having decreased albumin, increased globulins, and a more protracted increase in aminotransferases.[97,190,358] Acute autoimmune hepatitis is diagnosed by the absence of other causes for acute hepatitis and the presence of autoimmune markers (discussed in detail under chronic hepatitis). Wilson's disease is due to deficiency of an intracellular ATPase gene,[63,429] and typically presents with neuropsychiatric findings, often associated with chronic liver injury. Wilson's disease may also present as an acute hepatitis, often associated with fulminant hepatic failure[45]; in one study, 8 out of 14 patients who had hepatic injury due to Wilson's disease had an acute presentation.[179] The classic biochemical findings of Wilson's disease are often absent (low ceruloplasmin, low plasma copper, and Kayser-Fleischer rings) or misleading (high urine copper is common to all forms of acute hepatitis) in the setting of acute Wilson's disease.[45,417] A number of additional features are often present that suggest the diagnosis, including nonimmune hemolytic anemia,[183] acute tubular necrosis, and a ratio of ALP (in IU/L) to bilirubin (in mg/dL) of <2.[45]

Differential Diagnosis of Acute Hepatitis

There are several conditions that mimic the laboratory picture of acute hepatitis. Hemolytic anemia can cause jaundice, increased LD, and slight increases in AST and ALT. In contrast to hepatitis, the increase in bilirubin is predominantly (often >80%) indirect reacting. LD activity is elevated to several times that of AST, and AST activity is usually several times that of ALT. Acute skeletal muscle injury may cause significant increases in AST and, to a lesser extent, ALT, but the ratio of AST to ALT activity is generally more than 3:1,[322A] and bilirubin is usually not elevated. Acute bile duct obstruction, particularly when caused by gallstones, can cause a picture that resembles acute hepatitis. In the early stages of obstruction, transient increases in AST and ALT are common,[414] and rarely their activities may exceed 2000 IU/L.[24,157] Increases in ALP develop more slowly than those of the aminotransferases, masking the presence of cholestasis early in the course. Increases in bilirubin are typically predominantly direct reacting, creating a presentation similar to that seen in acute hepatitis. Even if obstruction persists, aminotransferase activity falls rapidly, with AST typically returning to normal within 8 days,[350] and ALP activity gradually increases if obstruction persists. ALP activities more than 300 IU/L in this setting strongly suggest the presence of obstructive jaundice.[458] Acute biliary obstruction by gallstones is often accompanied by acute pancreatitis; increased amylase and lipase should suggest biliary tract obstruction as the cause of any liver abnormalities noted.

Once a diagnosis of acute hepatitis is established, additional laboratory testing may be required to determine the etiology. Although the incidence of acute viral hepatitis has decreased, serological studies should be performed to rule out infectious causes. A typical panel of tests would include IgM anti-HAV, HBsAg, IgM anti-HBc, anti-HCV, and HCV core antigen or HCV RNA. Marked elevations (>100 times the upper reference limits) in either AST or ALT, particularly if AST is higher than ALT, should suggest the possibility of toxic or ischemic liver injury. Minimal increases (<8 times the reference limit) in AST, with AST greater than ALT, in a patient with jaundice and leukocytosis indicates likely alcoholic hepatitis. Imaging studies of the biliary tract are appropriate to rule out obstruction in those who present with sudden onset of symptoms, especially if accompanied by right upper quadrant pain and tenderness, laboratory evidence of pancreatitis, or a history of gallstones. The presence of increased globulins and decreased albumin, or the presence of hemolytic anemia and acute renal failure, should suggest the possibility of autoimmune hepatitis or Wilson's disease, respectively.

Follow-up of Acute Hepatitis

The important uses of laboratory tests in acute hepatitis are to identify individuals with fulminant hepatic failure, document recovery, and determine clearance of any infectious agents. The most important tests in determining extent of injury are not plasma activities of cytosolic enzymes, but evidence of impaired liver function. The most important indicator of prognosis in acute hepatitis is impairment in synthetic functions of which PT is a widely accepted indicator. In acute viral or alcoholic hepatitis, PT more than 15

seconds is associated with a poor prognosis,[337] whereas in toxic hepatitis persistent elevation more than 4 days after ingestion has prognostic importance.[189] Other markers of synthetic function, such as transthyretin, or markers of hepatocyte regeneration, such as alpha-fetoprotein, have been found to predict prognosis.[202] Although hypophosphatemia is common in fulminant hepatic failure, normal phosphate concentrations in this setting have been associated with worse prognosis.[90] Cytosolic enzyme activities decrease rapidly in ischemic and toxic hepatitis or obstruction, regardless of outcome, and fall more gradually in viral and alcoholic hepatitis, but are not helpful in evaluating outcome. With both hepatitis B and C, cytosolic enzyme activities may return to normal even if viral replication persists[112,216]; serological tests are the only reliable means to evaluate resolution of infection.

Chronic Hepatitis

Chronic hepatitis is defined as a chronic inflammation of the liver that persists for at least 6 months, or signs and symptoms of chronic liver disease in the presence of elevated cytosolic enzymes.[127] It is characterized by ongoing inflammatory damage to hepatocytes, often accompanied by hepatocyte regeneration and scarring. Formerly, chronic hepatitis was subdivided into three forms (chronic persistent, chronic lobular, and chronic active) based on histological characteristics. It was recognized that individuals often had each of these "diseases" at different points in time, and often in different areas of the liver in the same biopsy. Currently, classifications describe the etiology and grade both the current severity of inflammatory injury (termed grade) and extent of fibrosis (termed stage). The importance of these findings will be discussed in detail later. The common causes of chronic hepatitis and the tests used to make a specific etiological diagnosis are listed in Table 47-4.

The clinical features of chronic hepatitis are highly variable. Most patients are asymptomatic, but nonspecific features such as fatigue, lack of concentration, and weakness may be present. Most patients are diagnosed because of an unexplained abnormality of aminotransferases or detection of positive results on a screening test for a cause of chronic hepatitis. Moderate elevations of aminotransferase activities (twofold to fivefold) are characteristic, whereas results of most other tests are normal. Normal aminotransferase activities do not rule out histological evidence of chronic hepatitis, especially in the presence of chronic viral hepatitis or nonalcoholic steatohepatitis (NASH).[124,170,308] Characteristically, ALT is elevated to a greater degree than AST,[81] although elevations in both are common; reversal of the AST:ALT ratio to greater than 1 suggests coexisting alcohol abuse or development of cirrhosis[154,215,347] (as discussed in more detail later in this chapter). Although ALT is relatively specific for the liver, skeletal muscle sources for AST and ALT should always be considered, especially in physically active young individuals.[121,251,322A] Finding persistent elevation of aminotransferase activity should lead to an evaluation for chronic hepatitis using the tests outlined in Table 47-5. A liver biopsy may be helpful in determining etiology, assessing severity, and following treatment.[25] A specific etiological diagnosis is essential because it dictates the treatment. The most common causes of chronic hepatitis are chronic HBV and HCV and NASH, but a variety of other disease processes may cause chronic hepatitis.

TABLE 47-4 Causes of Chronic Hepatitis and Diagnostic Strategies

Cause	Diagnosis
Hepatitis B	History, HBsAg, anti-HBs, anti-HBc, HBV DNA
Hepatitis C	Anti-HCV, HCV RNA by PCR
Autoimmune type 1	ANA, anti-smooth muscle antibody
Autoimmune type 2	SLA, anti-LKM_1
Wilson's disease	Ceruloplasmin
Drugs	History
α_1-Antitrypsin deficiency	α_1-AT phenotype
Idiopathic	Liver biopsy, absence of markers

Chronic Hepatitis B

Worldwide, HBV infection is the most important cause of chronic hepatitis. Specifically, there are approximately 350 million individuals with chronic HBV infection worldwide, with most cases found in Asia, Africa, and southern Europe.

In most circumstances, HBV is not cytopathic, as the injury results from an immune-mediated inflammatory attack against the hepatocyte. Chronic hepatitis results when the immune response is incomplete and the virus is not eliminated from infected cells. This leads to a continuing cycle of viral replication, reinfection of regenerating hepatocytes, and immune damage to newly infected cells that is inadequate to clear infection. The details are not completely understood, but it appears that in the normal circumstance, hepatocytes express surface markers (in this case, HBcAg and HLA class 1 proteins).[311] Primed lymphocytes then attack the infected hepatocytes.[84] The expression of the HLA class 1 markers is stimulated by interferon. It appears that many chronic hepatitis B patients are deficient in or have an inadequate response to interferon and, by inference, are unable to express HLA antigens that would attract an appropriate lymphocyte response.[256] The discovery of interferon deficiency led to the successful use of α-interferon (IFN alpha) therapy in chronic hepatitis B patients. The clinical presentation may be complicated by a number of extrahepatic complications, including (1) polyarteritis, (2) glomerulonephritis, (3) polymyalgia rheumatica, (4) cryoglobulinemia, (5) myocarditis, and (6) Guillain-Barré syndrome.

TABLE 47-5 Tests for Evaluating Chronic Hepatitis C Infection and Its Treatment

Time of Testing	Test	Condition	Use/Interpretation
Pretreatment	HCV viral load	Detectable	Baseline (to compare to 12 wk value)
	Genotype	2 or 3 vs other	Length of treatment (24 wk genotype 2 or 3, 48 wk if other genotype)
12 wk on treatment	HCV viral load	<2 log drop	Stop treatment (nonresponder)*
		>2 log drop	Continue treatment (on treatment responder)
24 wk on treatment†	Sensitive HCV RNA‡	Detectable	Stop treatment (nonresponder)
		Not detectable	Continue treatment (on treatment responder)
End of treatment§	Sensitive HCV RNA‡	Detectable	Nonresponder
		Not detectable	Treatment responder
24 wk after completion	Sensitive HCV RNA‡	Detectable	Relapser
		Not detectable	Sustained virological responder

*Less than 3% chance of sustained virological response; some continue treatment to 24 weeks and reevaluate.
†Only done if genotype not 2 or 3.
‡Lower detection limit <50 IU/mL.
§Done at 24 weeks if genotype 2 or 3, done at 48 weeks in other genotypes; not all recommend evaluating end of treatment response.

These conditions are associated with circulating immune complexes containing HBsAg.[438] Immunocompromised patients, such as HIV-positive patients, typically have higher replication markers, less hepatic inflammation, and similar rates of survival.[233]

The natural history of chronic hepatitis B (defined by the persistence of HBsAg) varies. It is convenient to divide chronic hepatitis B infection into two basic types: replicative and nonreplicative. In the chronic replicative form, viral DNA is found in the cytoplasm of infected hepatocytes, and complete viral particles are produced and released into the circulation. In the replicating form of infection, viral loads in plasma are high ($>10^5$ copies/mL, often $>10^8$ copies/mL), and evidence of hepatocyte injury (elevated aminotransferase activity and inflammation in liver biopsy sections) is found in most cases. This variant has also been termed chronic hepatitis B. Approximately 3% to 5% of individuals with chronic replicating infection transform to the chronic, nonreplicating form yearly. In the nonreplicating form, HBV DNA becomes integrated into the host cell DNA, circulating viral load is low or undetectable, and evidence of hepatocyte injury is usually absent. This variant has also been termed HBV carrier state. Traditionally, HBeAg has been used to differentiate these two forms, with negative HBeAg and positive anti-HBe thought to indicate the nonreplicating stage of infection. As discussed earlier, however, it is common to find precore mutants of HBV that lack ability to form HBeAg. Even in individuals who were HBeAg positive in areas with low prevalence of precore mutants, loss of HBeAg may be due to development of precore mutants. Consequently, guidelines on HBV have been established that recommend measuring HBV DNA instead of HBeAg, particularly in individuals with evidence of hepatocyte injury.[135,267,447] A third variant of chronic HBV infection is termed the immunotolerant form; it is associated with HBeAg and/or high HBV viral load, but no evidence of hepatocyte injury. Immunotolerant forms of infection are common in vertically transmitted HBV for the first 2 decades of life, and in the early stages of chronic HBV infection in adults.

Although these three forms of infection represent the major variants of HBV infection, it is common for individuals to pass between the different variants. About 1% to 2% of individuals who are in the nonreplicating form will revert to the replicating form of infection. Another 1% to 2% will lose HBsAg and develop anti-HBs. Each of these transitions, along with transition from replicating to nonreplicating variants, can be associated with an acute rise in aminotransferase activities, increases in hepatocyte injury after a biopsy, and a clinical picture mimicking acute viral hepatitis.

For individuals who have chronic replicating infection, the major risk is development of cirrhosis and HCC. An estimated 30% of individuals with chronic hepatitis B will develop cirrhosis over a 20-year follow-up period. Once cirrhosis has developed, there is a 1.5% to 5% annual risk of development of HCC. Although the risk of HCC is lower in individuals with HBV infection who do not have cirrhosis, even a person in the nonreplicating stage of infection has a tenfold higher risk of HCC (compared with those who are HBsAg negative). On a worldwide basis, hepatitis B infection is the most common cause of liver cancer.

Two guidelines from the American and European hepatology societies summarize treatment recommendations.[267,447] Currently, three agents are approved for treatment of chronic HBV infection: interferon,* lamivudine, and adefovir dipivoxil.[186,277] The latter two are inhibitors of

*Interferon-alpha 2a and 2b have been extensively used and tested. Pegylated interferon is a newer formulation.

reverse transcriptase and have also been used to treat HIV infection. Other HIV treatment agents have been evaluated in research studies, but are not yet approved for use in North America or Europe. At present, only single agent therapy is used. With the low rate of response and development of lamivudine resistant mutants, trials are underway for evaluation of combination therapy, but results are generally not yet available. One large study of pegylated interferon and lamivudine found no additional benefit from combination therapy.[219A] Treatment is indicated for treatment of individuals with positive HBeAg and/or HBV DNA $>10^5$ copies/mL, particularly if they also have elevated ALT. Response rate is directly related to pretreatment ALT activity and is less than 10% in those with normal ALT. The goal of treatment is suppression of viral replication, detected either by undetectable HBV DNA or clearance of HBeAg and development of anti-HBe; approximately 20% to 30% of individuals treated will attain these goals. In patients who clear circulating virus, HBsAg becomes undetectable in up to a quarter of the cases.[122] This occurs almost exclusively in those with HBV DNA viral load $<10^3$ copies/mL.[309] Although clearance of circulating virus with interferon therapy seems to persist long term in 80% to 90% of responders, relapse is more common with lamivudine or adefovir. Even in this group who lose HBsAg and circulating HBV DNA, HBV DNA is often still detectable in liver cells.

Chronic Hepatitis C

There are approximately 170 million individuals with chronic HCV infection worldwide, with most cases found in North America, Northern Europe, and Japan. In addition, chronic infection follows acute infection much more commonly (among those exposed after age 5) among those infected with HCV than HBV.[19] There is evidence that chronic HCV infection actually develops in 50% of those with acute infection,[238,400,465] and that antibody titers decline and may become negative in those who clear infection.[374,399] Once viremia becomes established beyond 6 months after initial exposure, it essentially never resolves spontaneously; in one study of 320 patients followed serially more than 3 years, only 6 patients with end-stage liver disease lost detectable HCV RNA.[480] HCV viral load fluctuates little over time; in most individuals, viral load differs by less than 0.5 log,[177,187] and gradually increases by an average of 0.2 to 0.3 log/year.[141,328] It is estimated that approximately 20% of patients with hepatitis C will progress to cirrhosis over a period of 20 years.[397] The frequency of progression appears to be increased by age over 40 at time of infection, male gender, alcohol abuse, and immunosuppression,[276] but is less than 5% after 20 years of infection in those infected in the first 20 to 30 years of life.[238,374,399,400,465] As with HBV, the likelihood of progression to HCC is between 1.5% and 5% per year in those with cirrhosis.

The clinical picture of chronic HCV is similar to HBV in producing chronic hepatitis. In contrast to HBV, where ALT activity remains relatively constant with increases at time of seroconversion, infection with HCV is characterized by fluctuating ALT activities over time. Only about one third of those with chronic HCV have continually increased ALT, and many of these show variation in ALT activity.[126] It is common for individuals with fluctuating values to have multiple normal ALT activity values separating elevated values.[216,369] Also in contrast to HBV, individuals with continually normal ALT activity have a similar rate of response to antiviral treatment.[35]

Treatment of chronic HCV has changed from single agent treatment with interferon, with relatively low response rates, to treatment with a combination of pegylated (long-acting) interferon plus ribavirin. New agents, including protease inhibitors, have shown promise of increasing treatment response rates and providing a treatment option for those who fail interferon-based therapy. In contrast to HBV, where treatment is aimed at inhibiting viral replication, treatment of HCV is often successful in eradicating the virus. Hepatitis C viral clearance occurs in three stages; these are postulated to include clearance of circulating virus, loss of replication by cells, and clearance of infected cells. The third phase correlates best with viral clearance during treatment.[196] Several terms have been used to describe treatment response.[108] Early virological response refers to at least a 2 log decrease in viral load after 12 weeks of treatment. End of treatment response refers to undetectable HCV RNA at the end of a prescribed cours of therapy. Sustained virological response (SVR) refers to undetectable HCV RNA 6 months following completion of treatment. In those achieving SVR, long-term suppression of HCV RNA and resolution of chronic hepatitis occur in more than 99% of patients. A number of factors influence response to treatment. The most important is genotype; genotypes 2, 3, and 4 have response rates approximately twice those of other genotypes (SVR 70% to 80% versus 45%) and those infected by genotypes 2 and 3 require only 6 months of treatment rather than 12 months for other genotypes.[120] Response rates are lower in those of African ancestry, and in those at increased risk of developing fibrosis. In those who develop recurrent HCV after liver transplantation, response rate is lower and rate of progression to cirrhosis is faster than in primary infection. Table 47-5 summarizes laboratory tests used to evaluate and monitor treatment for HCV.

Nonalcoholic Fatty Liver Disease and Nonalcoholic Steatohepatitis

Ludwig first described patients who had histological features identical to alcoholic hepatitis, but who had no history of alcohol abuse and did not have AST higher than ALT.[271] He introduced the term "nonalcoholic steatohepatitis" (NASH) to describe this entity that was more common in women than men and usually was associated with diabetes and/or obesity. (Since alcohol ingestion is common in the population, and alcoholic liver disease does not occur with ingestion of less than 20 g ethanol daily, this threshold has been suggested as the maximum alcohol intake compatible with a

diagnosis of nonalcoholic fatty liver disease [NAFLD]).[326] The disease can also occur in men and in those without diabetes or obesity. Although NASH represents a necroinflammatory liver disease, there is increasing recognition that fat accumulation in the liver without inflammation is also commonly found in individuals with obesity and diabetes, and those with other components of the metabolic syndrome.[278] The more encompassing term NAFLD has been introduced to include this latter form and NASH. NAFLD is defined as the presence of fat accumulation to greater than 5% to 10% of liver mass, usually recognized upon biopsy as increased cytoplasmic fat. Although ultrasound can also be used, it is insensitive to fat content less than 25% of liver mass.[408]

Current evidence suggests that accumulation of fat in NAFLD is a consequence of insulin resistance.[326] A variety of mechanisms may lead to insulin resistance, including genetic predisposition, increased concentrations of free fatty acids, and presence of cytokines such as tumor necrosis factor alpha (TNF-α). Since TNF-α is produced by fat cells, correlates with body fat, and is critical to development of insulin resistance in obesity,[446] it may be a key factor in development of NAFLD. The pathogenesis is likely to be more complicated, however, as a variety of other factors lead to increased fat accumulation in the liver, including increased carbohydrate intake, certain drugs, and mutations in lipid synthesis, but have not been associated with development of NASH.

The frequency of NAFLD is high in North America and Europe; it has been estimated that NAFLD occurs in 20% of the population and NASH in 2% to 3%; this would make NASH as common as chronic HCV as a cause of chronic liver disease. Prospective studies of patients with liver disease have confirmed that NASH is a common cause of elevated liver enzymes in an unselected population of patients referred to gastroenterologists or seen in primary care settings.[70,107,285] The frequency in obese or diabetic individuals is much higher, with NAFLD in 60% to 75% and NASH in 20% to 25%.[326,459] Although simple fat accumulation is thought to be benign, and most cases of NASH are associated with minimal fibrosis, NASH has progressed to cirrhosis in 15% of cases in the small number of published prospective studies. The frequency of cirrhosis in NASH is not well established, but there is a suggestion that NASH may be a major cause of "cryptogenic" cirrhosis, in which no underlying etiology can be determined. As weight loss develops with chronic illness, fat may disappear from the liver, leaving only fibrosis.

Laboratory diagnosis of NASH and NAFLD is not currently possible. The clinical features of NASH are nonspecific, similar to those of other causes of chronic hepatitis. Although increased activities of liver enzymes are often used to distinguish NASH from other forms of NAFLD, the degree of necroinflammatory damage is not related to elevations of AST or ALT activity, and the likelihood of significant liver damage is similar in those with normal or elevated ALT.[308]

To date, the major treatments for NAFLD have been those aimed at lowering body weight and fat content. Loss of weight is often associated with decreased ALT values; in one study, a 1% decrease in weight was associated with an 8% decrease in ALT activity.[344] The association of NAFLD with insulin resistance has suggested treatment with antidiabetic medications, particularly those that increase insulin responsiveness (such as PPAR-γ receptor agonists and metformin), but there are no conclusive studies that document safety and efficacy.

Autoimmune Hepatitis

Autoimmune hepatitis (AIH) represents a rapidly progressing form of chronic hepatitis, with up to 40%, 6-month mortality in untreated individuals[412] associated with the presence of autoimmune markers. Although typically a chronic disease, it may have an acute presentation in up to 40% of cases, as discussed earlier. It is relatively uncommon, with an annual incidence of 1.9 cases per 100,000 population,[51] but it is responsible for 3% to 6% of all liver transplants.[302,467] As with most autoimmune diseases, there is a strong female predominance. Forms of AIH can be found in all age ranges, with no racial or ethnic predilection. There are associations with specific HLA haplotypes, notably DR3 and DR4, as is true for many other autoimmune diseases. Practice guidelines on autoimmune chronic hepatitis have been developed by the American Association for the Study of Liver Diseases (AASLD).[103] Immunosuppressive treatment using prednisone, alone or in combination with azathioprine, is effective in inducing a clinical remission of disease in about 80% of cases. Since there are inherited differences in activity of thiopurine methyltransferase that affect about 10% of the population,[259] it has been recommended that pretreatment determination of enzyme activity be used to reduce the likelihood of toxicity.[194] Remission typically begins with improvement in symptoms, followed by normalization in laboratory abnormalities, and finally histological resolution.[103] Laboratory remission generally does not occur until at least 12 months of treatment, but almost always occurs by 24 months in responders. Histological remission is less common and usually requires at least 3 to 6 months longer than laboratory evidence of remission.[412] Sustained remission can persist off treatment in 80% of those with normal histology following therapy, but relapse occurs in 50% within 6 months if inflammation persists in the liver biopsy.[102]

AIH is associated with the presence of liver- and nonliver-related autoantibodies in plasma. These are helpful in diagnosis, but are not likely to be the cause of liver injury. The most important antibodies for diagnosis include antinuclear antibody (ANA), antismooth muscle antibody (ASMA), and antiliver-kidney microsomal antigen type 1 (LKM_1). A variety of other autoantibodies are found frequently in AIH, some of which are found in other disorders. A summary of the most common autoantibodies, their associations, and their molecular targets (when known) is given

TABLE 47-6 Serological Markers of Autoimmune Liver Disease

Antibody Name	Antigen target	Associations
Anti-actin	Actin	AIH type 1; more specific than ASMA, poor response to corticosteroids, early age onset
Anti-asialoglycoprotein receptor (ASGPR)	Transmembrane antigen binding protein	AIH, correlate with activity, disappear with successful treatment
Anti-liver kidney microsome (LKM_1)	Cytochrome P450 IID6	AIH type 2; seen in only 4% of U.S. cases; usually in children
Anti-liver specific cytosol (LC_1)	Enzyme (possibly formimino-transferase cyclodeaminase or argininosuccinate lyase)	AIH in younger patients, often with anti-LKM_1, primary sclerosing cholangitis; vary with activity of disease
Antimitochondrial antibody (AMA M2 type)	Dihydrolipoamide acyltransferase	Primary biliary cirrhosis
Antineutrophil cytoplasmic antibodies (p-ANCA)	Bactericidal/permeability protein, cathepsin G, lactoferrin	Primary sclerosing cholangitis (50%-70%), ulcerative colitis (50%-70%), AIH; nonspecific
Antinuclear antibody (ANA)	Multiple targets (centromere, ribonucleoproteins); may not be detected by ELISA	AIH type 1, some PSC cases
Antismooth muscle antigen (SMA)	Actin, tubulin, vimentin, desmin, skelitin	AIH type 1, seen in other autoimmune diseases in lower titers
Antisoluble liver antigen/liver pancreas (SLA)	Selenocysteine pathway protein (? serine hydroxymethyltransferase)	AIH type 3; very specific for AIH, correlate with relapse after corticosteroid withdrawal

AIH, Autoimmune hepatitis.

in Table 47-6. Tests for these autoimmune markers have typically used cell or tissue preparations studied by indirect immunofluorescence. With identification of target antigen(s) in tissue, assays have been developed to detect antibodies to these purified proteins. Such assays can be helpful in diagnosis, but the information derived from purified antigens is not always equivalent. Many laboratories currently use panels of purified antigens to detect antinuclear antibodies and many individuals with AIH are positive with tissue ANA tests, but negative using a panel of the most commonly found antinuclear antigens.[104] Antibodies to actin are the most common cause of ASMA; although they are more specific for AIH and may have stronger prognostic importance, they are less sensitive than ASMA and are not recommended for diagnostic use.[101]

Criteria for the diagnosis of AIH have been developed by an international group[223] and have been revised to improve their use.[21] The criteria include: (1) exclusion of other causes of liver injury; (2) elevation of aminotransferases with minimal increase in ALP; (3) presence of elevated immunoglobulins; positive ANA, ASMA, or anti-LKM_1, with negative antimitochondrial antibody; (4) compatible histological features; and (5) absence of intrahepatic bile duct injury. A scoring system based on these criteria has also been established; this has allowed recognition of overlap syndromes that have features of both AIH and autoimmune bile duct destruction, but is not needed in most cases to establish the diagnosis.[103]

It is controversial whether AIH should be further divided into subtypes; the international group that codified diagnostic criteria does not recommend use of subtypes,[21] but many authorities recognize three different forms. Although there may be differences in epidemiology among the different forms, there do not seem to be differences in clinical course or response to treatment. Type 1, which is the most common form and the only one seen frequently in North America, is predominantly a disease of middle-aged women. It is characterized by ASMA (found in 87% of cases) and/or ANA (found in 67% of cases); one or the other is present in nearly 100% of cases. Because of the nonspecific nature of these antibodies, titers are important in determining likelihood of AIH. In adults, positive antibodies in titers greater than or equal to a 1:80 dilution are supportive of the diagnosis, whereas lower titers are not.[21] In children, titers are typically lower than those seen in adults. Type 2 AIH, which characteristically occurs in children (although 20% occurs in adults), represents up to 20% of cases in Europe.[201] It is associated with antibodies to liver-kidney microsomal antigen 1

(anti-LKM_1) or cytochrome P450 2D6 (CYP2D6).[489] There is some cross reactivity between this antibody and certain HCV antigens, leading to positive anti-CYP2D6 in individuals with HCV infection. The epitopes recognized by anti-HCV antibodies are different from those in person with type 2 AIH.[273] Type 3 often lacks other autoimmune markers, but is positive for antibody to soluble liver antigen liver/pancreas. This antibody appears to be directed against a component in the selenocysteine pathway and has been suggested to be an enzyme.[239]

Inherited Liver Diseases Presenting as Chronic Hepatitis

Inherited liver diseases that present as chronic hepatitis include hemochromatosis, Wilson's disease, and $alpha_1$-antitrypsin (AAT) deficiency.

Hemochromatosis

Hereditary hemochromatosis (HH) is an autosomal recessive disorder of iron metabolism that results in excessive iron absorption and accumulation in tissue (see Chapter 31). The gene for HH has long been linked to chromosome 6, close to the genes for the HLA system; initially the gene was termed HLA-H. This gene has now been definitively identified and termed the HFE gene; it codes for a transmembrane protein similar to the class I MHC molecule.[149] The protein is located on the endothelial side of intestinal epithelial cells and binds transferrin-transferrin receptor complexes in some fashion, signaling a stop to iron absorption.[355] The process of iron absorption is complex.[354] At the luminal border, iron must be reduced to ferrous iron by a duodenal cytochrome enzyme termed Dcytb. Iron is then transported across the brush border by the divalent metal transporter DMT1. Iron can then be stored as ferritin, or transported across the basolateral membrane by ferroportin 1 (FP1). Iron is then oxidized by hephaestin (Hp), a transmembrane ferroxidase with 50% homology to ceruloplasmin. Ferric iron is then bound to transferrin for delivery to iron-dependent cells. The loop is completed, in the case of the duodenum, through cellular iron response proteins (IRP) that bind to iron-responsive regions (IRE) in RNA, altering translation. HFE mutations are associated with increased expression of DMT1 and FP1 in duodenal villus epithelial cells. What is not yet clear is how HFE mutations alter iron absorption, since HFE is highly expressed in crypt cells, but not in villus cells.

In North America and Europe, more than 90% of individuals with HH are homozygous for a single point mutation that inserts a tyrosine instead of cysteine at residue 282 (termed the C282Y mutation). A small percentage of cases are homozygous for a more common mutation, causing replacement of histidine with aspartate at residue 63 (H63D), or are compound heterozygotes for C282Y and H63D.[430] Homozygosity for C282Y is one of the most common genetic traits; it occurs primarily in individuals of northern European ancestry, where the gene frequency is approximately 1 in 8, and the homozygous state is found in 1 in 150 to 200.[53] It is less frequently seen in other populations; in African-Americans, the frequency is 1 in 10,000.[40] Other mutations in the HFE gene have also been linked to hemochromatosis,[49,316,418] but in some populations inherited defects in HFE have been excluded,[356] and mutations in other proteins that regulate iron absorption have been identified.[72,334,356A]

Identification of the HFE gene mutations has led to a number of screening programs for HH. These studies have confirmed the high frequency of the gene, and documented increased transferrin saturation and ferritin in most homozygous individuals.[9,48,65,341] Based on these gene frequencies, hemochromatosis should be a relatively common disease; however, it has long been considered rare. In a study from the Netherlands (an area of high prevalence of homozygous HFE mutations), the prevalence of clinically diagnosed hemochromatosis was 1.4 cases per 100,000 population before testing for the HFE gene was instituted.[304] There is no difference in the frequency of homozygosity for the C282Y mutation with increasing age through the first 70 years of life, with only a slight decrease in gene prevalence after age 80, suggesting that the gene has only a minimal effect of longevity.[42,48] In one study, in which those screened had an average age of 57 years, there was only a twofold increase in the frequency of increased liver-related enzymes or history of liver disease when compared with controls.[48] There is no difference in the frequency of symptoms linked to hemochromatosis in homozygotes when compared with those with the wild-type gene.[454] The penetrance of the gene has been estimated at only 1%.[48,289] This has led some to question whether other factors are involved in the development of the disease and whether screening for the HFE gene is advisable.[7,53] For example, excess alcohol intake is strongly linked to risk of development of cirrhosis in individuals homozygous for the C282Y mutation.[153] Practice guidelines developed by the AASLD do not advocate screening.[430]

The key clinical laboratory features of hemochromatosis are related to excess iron; iron testing is discussed in more detail in Chapter 31. Since plasma iron increases relatively rapidly after meals, it is advisable to either use fasting samples for initial testing, or confirm elevated values on a fasting sample before doing further testing for evidence of iron overload. Several studies have shown that a cutoff value of transferrin saturation (plasma iron divided by total iron binding capacity) greater than 45%, or unsaturated iron binding capacity less than 155 μg/dL (28 μmol/L) has a clinical sensitivity of close to 100% for detecting homozygous C282Y mutations.[9,341] The positive predictive value of these cutoffs for homozygous mutations ranges from 20% to 70%.[292,341] Individuals lacking HFE gene mutations typically have average transferrin saturation approximating 25%.[292,341] Plasma ferritin has been used as a test for iron overload; it is not as sensitive as plasma iron indices in most studies[9,341] and is increased by tissue injury independent of iron stores. In a large screening program in which genotype was determined,

ferritin was increased above the 90th percentile of healthy individuals in only about 60% to 70% of males and females,[246] whereas transferrin saturation was above the 90th percentile in almost 80% in both genders. Individuals with both increased transferrin saturation and increased ferritin have a higher likelihood of having genetic hemochromatosis. A liver biopsy with quantification of hepatic iron has been considered the standard for diagnosis of iron overload. It is best interpreted as the hepatic iron index {liver iron {μmol/g liver (dry weight)} divided by age (y)]; values of 1.9 or over indicate excess iron. Hepatic iron index correlates well with genetic evidence of hemochromatosis, but is not as clinically sensitive as plasma tests[8,236]; guidelines suggest it has little use in diagnosis when genetic markers are available.[36,430] At present, the key to diagnosis of HH is by documentation of gene mutations in the HFE gene. This is most commonly done by PCR, but a variety of techniques are available to detect the two most common mutants. It has been reported that insignificant mutations in other regions of the normal HFE gene may prevent its amplification in vitro, leading to false interpretation of homozygosity for the abnormal gene.[117,221]

When present, clinical manifestations of hemochromatosis are variable. The classical triad of hemochromatosis consists of cirrhosis, diabetes mellitus, and bronzing of the skin. The frequency of homozygous C282Y mutations is increased in individuals with type 2 diabetes mellitus. The skin pigmentation is a result of melanin, not iron, deposition. Cardiomyopathy is another serious complication of hemochromatosis and may be the dominant clinical manifestation. With screening, it has become apparent that less classic presentations, such as abdominal pain, arthritis, and hypogonadism, are relatively common. Other endocrine problems, such as hypopituitarism and hypoparathyroidism, typically occur late in the course of disease. Although plasma iron indices are similar in men and women, clinical manifestations of hemochromatosis typically occur at a later age in women, presumably because of ongoing iron loss with menstrual bleeding.

Therapy for HH involves phlebotomy to remove excess iron and stimulate erythropoiesis to use stored iron. An average phlebotomy removes approximately 250 mg of iron. The goal of treatment is to induce iron deficiency, defined by plasma ferritin below 20 ng/mL. Phlebotomy is initially performed weekly until iron deficiency develops; this may require a year or more in individuals with advanced iron overload. Once iron deficiency has been obtained, most patients will require regular phlebotomy to maintain normal plasma iron indices.

Wilson's Disease

Wilson's disease is an autosomal recessive disorder of copper metabolism (see Chapters 20 and 30). It has a gene frequency of 1 in 200 and a disease frequency of 1 in 30,000. It is due to one of more than 200 mutations in a gene on chromosome 13 coding for a copper transporting ATPase (ATP7B).[63,429] This enzyme, found mainly in the liver, is involved in movement of copper into bile; deficiency leads to accumulation of copper in the liver and, eventually, in other tissues. Low plasma concentrations of ceruloplasmin, a copper containing enzyme made in the liver, are also characteristic of Wilson's disease. With deficiency of ATP7B, apoceruloplasmin does not gain its full complement of copper molecules before release from hepatocytes. Although originally low ceruloplasmin was thought to be the cause of Wilson's disease, apoceruloplasmin has a reduced half-life compared with the holoenzyme, leading to lower plasma concentrations.[200]

Wilson's disease usually manifests before age 30, although several patients in their 50s and 60s have been reported. For reasons that are unknown, patients usually have predominantly either the hepatic or neuropsychiatric form of the disease. In children, hepatic involvement tends to predominate,[482] whereas in adolescents and adults, the neuropsychiatric form becomes more common. The hepatic manifestations include fulminant hepatitis (as discussed earlier), but more commonly chronic hepatitis, with or without cirrhosis, is the presenting finding.[390,395] Occasionally the features mimic those of autoimmune hepatitis, with increased globulins and positive ANA.[303] Neurological findings are variable; the classic picture includes cog wheel rigidity, associated with degenerative changes in the basal ganglia on imaging studies.[419]

The classic clinical finding of increased copper deposition in the eye is the Kayser-Fleischer ring, caused by deposition of copper in Descemet membrane at limbus of the cornea. Although found in about 95% of patients with neurological or psychiatric manifestations, it is present in only about half of patients with hepatic forms of Wilson's disease[417] and is rarely present in children.[388] As mentioned earlier, hemolytic anemia and renal failure commonly accompany acute forms of Wilson's disease; hemolytic anemia may be episodic even in chronic forms of Wilson's disease.[372]

Several laboratory tests are available for diagnosis of Wilson's disease; ceruloplasmin measurement is discussed in detail in Chapter 20 and copper measurement in Chapter 30. Test results are often affected by other conditions, sometimes making diagnosis difficult. The classic findings of Wilson's disease are (1) decreased ceruloplasmin, (2) decreased total plasma copper, (3) increased plasma free (or nonceruloplasmin) copper, (4) increased urine copper excretion, and (5) increased hepatic copper content. Ceruloplasmin is a ferroxidase and typically measured either by enzymatic activity or by immunoassay. Although there has been controversy over which type is preferable, guidelines have not specified one type of assay.[127,372] Ceruloplasmin is very low in infants, gradually rises to higher than adult concentrations in early childhood, then gradually declines to adult concentrations. Use of age-appropriate reference intervals is critical for diagnosis in children. Ceruloplasmin is an acute phase protein, and its synthesis is induced by estrogen; concentrations may be falsely normal with acute illness or with high estrogen states.

Low concentrations of ceruloplasmin are seen with malnutrition, in protein losing states, and in cirrhosis of any cause. These preanalytic variables cause ceruloplasmin to have a low predictive value as a single test for Wilson's disease; in one study, the positive predictive value was only 6%.[77] Ceruloplasmin is also decreased in about 20% of heterozygous carriers of the Wilson's disease gene.[172] Because most plasma copper is bound to ceruloplasmin, total plasma copper is affected by factors that affect ceruloplasmin. Some estimate free (nonceruloplasmin) copper from total copper and ceruloplasmin as the difference between total copper (μg/dL) and [3 times ceruloplasmin (mg/dL)]; values more than 25 μg/dL suggest Wilson's disease.[164] Urine copper excretion is the most specific noninvasive test for Wilson's disease; 24 hour urine copper excretion is typically more than 100 μg/d in Wilson's disease. Unfortunately, clinical sensitivity of copper excretion appears to be only 75% to 85%.[388,417] A liver biopsy is thought to be the most reliable test for diagnosis of Wilson's disease. A copper content of >250 μg/g dry weight is fairly specific for Wilson's disease, except in the setting of chronic cholestasis, which should not cause difficulty in the differential diagnosis.[372,417]

Although genetic testing for Wilson's disease is possible, the large number of mutations, and the fact that most individuals with Wilson's disease have compound heterozygosity for two different mutations, makes genetic testing impractical for diagnostic purposes. In contrast, genetic testing of the proband is critical in determining the mutations present to allow screening of first degree relatives.[372]

Treatment of active, symptomatic Wilson's disease is aimed at increasing urine copper excretion to eliminate excess copper from tissue. The primary therapy for Wilson's disease involves chelating agents such as D-penicillamine and trientine, which is now more widely used because of its lower rate of side effects. In patients with minimal symptoms or in asymptomatic family members, zinc is used to competitively inhibit copper absorption from the intestinal tract. Lifelong therapy with one of these types of treatment is required and is usually successful in limiting further damage.

Alpha$_1$-Antitrypsin Deficiency

AAT is the most important of the serine protease inhibitors (collectively termed serpins), which include such proteins as antithrombin, plasminogen activator inhibitor, α_1-antichymotrypsin, and C_1 esterase inhibitor (see Chapter 20).[475] As its name implies, AAT inhibits trypsin, but also inhibits other proteolytic enzymes, including neutrophil-derived elastase, cathepsin G, and proteinase 3. The gene for AAT is located on chromosome 14. There are a number of genetic variants of AAT (differing by a single amino acid) that were originally classified on the basis of their electrophoretic mobility; the slowest migrating of these was termed the Z variant. Each individual has two copies of the protease inhibitor (Pi) gene, which can lead to several phenotypic variants. Some of the variants, particularly S and Z, form loop sheet polymers.[268] This leads to impaired release from the endoplasmic reticulum and hepatocytic inclusions of AAT, and reduced plasma concentrations, increased proteolytic damage to tissue, and clinical manifestations of disease. The most severe forms of disease have been associated with homozygosity for the Z variant (PiZZ), present in 1 in 1000 to 2000 individuals in Europe and North America.[208] (See Chapter 20 for additional information on AAT and its measurement.)

The major clinical manifestation of AAT deficiency is emphysema, which tends to occur at an earlier age and can occur in the absence of smoking. It is estimated that 1% of emphysema is related to AAT deficiency. In neonates, AAT deficiency is often associated with hepatitis; in one study, almost one third of infants with prolonged jaundice were found to be AAT deficient.[486] About 20% of AAT deficient infants develop hepatitis,[359] with up to 25% 1-year mortality.[207] In those who survive the first year, however, evidence of liver injury diminishes and usually resolves by age 12.[422,457] At age 18, none of 183 individuals with AAT deficiency had clinical evidence of liver disease, none had elevated procollagen III peptide, and less than 20% had elevated liver-associated enzymes.[423] These findings suggest that AAT may have minimal effects on pathogenesis of liver disease in adults.[402]

Actual data on association of AAT deficiency with liver disease in adults are somewhat contradictory. In several studies, cirrhosis was present in one third to one half of those with AAT deficiency, and HCC was present in about one third of those with cirrhosis.[138,367] The frequency was similar in those with heterozygous and homozygous presence of the PiZ variant.[367] In two studies of patients with cryptogenic liver disease, the frequency of the PiZ heterozygotes was significantly higher than found in the general population.[73,181] Two other studies, however, found a similar frequency of liver disease in those with AAT deficiency and controls.[152,312] Some evidence suggests that AAT deficiency may increase risk of liver damage from other factors. In one study, most individuals with AAT deficiency and liver injury were also positive for anti-HCV; only 11% had no other liver risk factors.[366] In those with AAT deficiency and no evidence of liver disease (usually viral related), life expectancy was no different from that in healthy controls.[366]

Estimation of AAT can be performed by protein electrophoresis, where it comprises most of the α_1-globulin band; this was the original means by which AAT deficiency was recognized.[138] AAT is quantified by a variety of techniques (see Chapter 20). AAT is an acute phase response protein; falsely normal quantitative concentrations have been reported in about 40% of PiZ heterozygotes,[199] although rarely in PiZZ homozygotes. Determination of phenotype is typically accomplished by isoelectric focusing, and has been recommended as the diagnostic test of choice in one guideline.[129]

Drug-Induced Liver Diseases

As discussed earlier, most cases of drug-induced liver disease present as acute hepatitis. Less commonly, drugs have produced a chronic liver injury, in a pattern mimicking chronic hepatitis or other chronic liver injury (chronic

cholestasis and hepatic granulomas).[396] The most common drugs linked to chronic hepatitis are nitrofurantoin, methyldopa,[255] and HMG-CoA reductase inhibitors[456]; however, a large number of drugs have been associated with liver injury,[496] and herbal medications have also been linked to chronic hepatitis.[85,416] In individuals with increased activities of aminotransferases and no obvious cause, prescription drug use was significantly more likely to be present than in those with a known cause for elevated enzyme activities.[284] As with acute drug reactions, establishing drugs as the cause of chronic hepatitis is difficult[176]; temporal relationships to drug ingestion are not as clear as with acute hepatitis, and reactions can first be seen in those who have been taking the medication for many months.[265] Most chronic drug reactions resolve when administration of the drug is discontinued.[11,22]

Significance of Chronic Hepatitis

Chronic hepatitis is, in many cases, a disease with minimal consequences. As mentioned earlier, an average of 20% to 30% of individuals with chronic HBV or HCV progress to cirrhosis over a 20-year period. However, cirrhosis is the 10th leading cause of death in the United States.[133] The frequency of cirrhosis and HCC has been increasing in much of the western world,[242] thought mostly caused by the increase in cases related to HCV. The proportion of individuals with HCV with cirrhosis and HCC is expected to double over the next 20 years, and the number of deaths caused by liver disease is expected to almost triple.[109] The ability to predict which patients are at increased risk for such late complications of chronic hepatitis would allow more appropriate treatment.

Fibrosis and necroinflammatory activity are the two major components of chronic hepatitis. The extent of fibrosis (stage) is strongly related to risk of progression,[212,346,478] whereas necroinflammatory activity (grade) is correlated with progression in some,[169,286,478] but not all,[75,360,363] studies. Since ALT activity is strongly correlated with necroinflammatory activity,[288] it is also associated with risk of progression to cirrhosis in some, but not all, studies. Clinical variables are also associated with risk of progression; these include age at infection, male gender, alcohol intake, and presence of immunosuppression.[75,160,281,364]

The process of scar formation in the liver involves a number of factors, and differs in some important ways from that in other sites in the body.[14,324,394] There is increasing evidence that the process of fibrosis is reversible, even when cirrhosis is histologically present.[131,132] For example, two studies have found that successful treatment of HBV[123] and HCV[362] was associated with reversal of cirrhosis in 50% to 75% of cases. Although the principal component is type III collagen, other components include type I and type IV collagen, laminin, elastin, and fibronectin. Proteoglycans, especially hyaluronate, are also part of scar formation. Production of scar in the liver is also affected by the rate of enzymatic degradation; a variety of matrix metalloproteinases (MP) are found in areas of scar formation, and there are several tissue inhibitors of metalloproteinases (TIMP) as well.[33] MPs are involved in degradation of the normal connective tissue of the liver (a necessary prequel to fibrosis), but are also involved in breakdown and remodeling of collagen. Hepatic stellate cells are critical in this process; they produce both MP and TIMP,[44] and collagen and other matrix materials.[381] Recruitment and activation of stellate cells involves the action of a number of cytokines, particularly TGF-β, platelet derived growth factor (PDGF), and interleukin-6 (see Chapter 22).[64,280,440]

These observations led to the expectation that measurement of plasma concentrations of factors associated with scar formation would correlate with the degree of fibrosis found in the liver biopsy. There appears to be significant overlap in concentrations of such markers between individuals with cirrhosis and those with varying stages of fibrosis in chronic hepatitis.* There is also evidence that marker concentrations change with alteration in necroinflammatory activity and may actually reflect activity of disease at the time of sampling, rather than cumulative fibrosis.[442] Subsequent interest has therefore focused less on using fibrosis markers to detect progression to cirrhosis and more on identifying individuals with minimal fibrosis, who have little risk of progression to cirrhosis. Calculation of a predictive index using a combination of 5 markers (α_2-macroglobulin, apolipoprotein A_1, total bilirubin, γ-glutamyl transferase (GGT), and haptoglobin) was highly effective in predicting those persons who did not have significant fibrosis.[214,318,361] This calculation requires use of the specific assays used in the initial studies; use of kits from other manufacturers led to poor performance of the predictive index.[378] Another predictive index using age, GGT, cholesterol, and platelet count had a similarly high negative predictive value,[156] but has not been validated in other laboratories. A combination of three markers (hyaluronate, TIMP-1, and α_2-macroglobulin) also showed high specificity in detecting fibrosis, but produced indeterminate results in 20% of individuals tested.[349]

Alcoholic Liver Disease

Alcoholic liver disease differs clinically and biochemically from other forms of hepatitis and liver disease. It is a common cause of liver disease in the developed world but the incidence of acute alcoholic hepatitis seems to be declining in North America and Europe.[275B] Risk factors for developing alcoholic liver disease include:[161A]

1. Duration and magnitude of alcohol ingestion. Alcoholic liver disease does not occur in all individuals with chronic ethanol intake, but there is a threshold intake of 40 g/day in men and 10 g/day in women below which alcoholic hepatitis does not occur.[298] For most individuals, the risk dose is about 80 g of alcohol (200 mL of whiskey or equivalent) per day.[258A] Daily drinking appears to be riskier than intermittent drinking.

*References 154, 163, 214, 335, 357, 437.

2. Gender. In women there is a greater likelihood of progression to cirrhosis and women have reduced activities of alcohol dehydrogenase in gastric mucosa, leading to increased blood levels of alcohol.[423A]
3. Hepatitis B or C infection. Both may increase the severity in the patients who drink heavily. For example, antibodies to HCV are several times more common in individuals with alcoholic hepatitis than in alcoholics without hepatitis or in age and gender matched controls, suggesting a synergistic role for HCV.[295]
4. Genetic factors. As discussed below, inherited predisposition to alcoholism has been clearly established.
5. Nutritional status. Protein-calorie malnutrition is extremely common in alcoholics. Malnutrition may be due not only to poor intake but also to abnormal nutrient metabolism. Whereas poor nutrition may contribute to the evolution of alcoholic liver disease, adequate nutrition does not prevent its development. In fact, studies suggest that obesity may be a risk factor.

In addition, there is evidence for an immunological component in alcoholic liver disease,[161,217,242A] and there is evidence that modification of liver proteins by ethanol metabolites is involved in the pathogenesis.[6,431] Acute alcoholic hepatitis clinically is an acute febrile illness, characteristically associated with leukocytosis[294] and increased concentrations of acute phase response proteins.[184] It also causes mild increases in cytosolic enzymes; AST activity is typically more than two times that of ALT[92] and it is rare for AST to be more than eight times the upper reference limit.[294] A cholestatic form of the disease, with increases in ALP activity to greater than three times the upper reference limit, is seen in up to 20% of cases;[333] it is associated with higher mortality. Increases in bilirubin are common, and reduced liver synthesized protein concentrations are also commonly present. Increased bilirubin, decreased albumin, and prolonged PT are poor prognostic markers in alcoholic hepatitis.[174] A discriminant function [4.6 × (PT – control PT)] + plasma bilirubin (mg/dL)] value >32 indicates individuals with a high mortality rate,[298] and a Model for (or Mayo) End Stage Liver Disease (MELD) score more than 11 has also been found to have similar sensitivity and better specificity.[403]

Both alcoholism and susceptibility to the development of cirrhosis appear to be largely genetically determined in that only 10% to 15% of heavy consumers of alcohol develop cirrhosis. Much effort has been expended in finding specific genetic markers and it has been found that the rate of cirrhosis is much higher if a patient has a parent with alcoholic cirrhosis.[151A] Whitfield and colleagues have confirmed these findings as they have found that variation in alcohol intake is due to genetic effects.[463A,463B] In addition, genes affecting intake also affect dependence risk, but there are other genes that affect dependence alone. The predisposition may be related to different rates of alcohol elimination, which are determined by genetic polymorphism of the microsomal ethanol oxidizing system (MEOS) and alcohol dehydrogenase (ADH).[425A,463B] For example, 50% of Asians have absent alcohol dehydrogenase, leading to a flush reaction to alcohol that inhibits drinking and thus is a negative risk for alcoholism. Alternatively, heterozygotes of the acetaldehyde dehydrogenase (AADH) gene have impaired clearance of acetaldehyde, the putative toxin of alcohol, and may be at increased risk for liver injury. Two forms of alcoholism have been identified in the Stockholm Adoption Study.[408A] Type 1 has adult onset and rapid progression of dependence. Type 2 has teenage onset with recurrent social and legal problems.

Alcohol is metabolized to acetaldehyde by cytosolic ADH and the MEOS (primarily CYP 2E1—the same cytochrome P_{450}–dependent enzyme involved with acetaminophen metabolism). Acetaldehyde is subsequently metabolized to acetyl-CoA by AADH. This is further broken down to acetate, which is either converted to carbon dioxide and water or enters the citric acid cycle to be converted to fatty acids. The latter is a major mechanism for induction of fatty liver by alcohol, but acetaldehyde is probably the primary toxin. It causes most of the injury to liver cells as well as the induction of collagen synthesis leading to fibrosis and, ultimately, cirrhosis.

A large number of biochemical markers have been proposed for the detection of excessive alcohol consumption and associated liver disease.[95A,95B,151A,175A,220A,252A,253A,301B] Clinically, aminotransferase activities rarely exceed 300 U/L in acute alcoholic hepatitis, and are much lower (and frequently within reference intervals) in chronic alcoholic liver disease. Alcohol depletes vitamin B_6–dependent pyridoxal-5-phosphate, an essential precursor of aminotransferase synthesis. The AST : ALT ratio is usually greater than 2, unlike in other liver diseases, in which ALT is typically higher than AST. This has been attributed to the increased appearance of mitochondrial AST (mAST). Although mAST is elevated in serum from alcoholics, it rarely accounts for >20% of total AST activity and is unlikely to be the sole cause. The higher AST may reflect damage to other tissues that release AST but not ALT, which is confined to the liver. ALP is typically elevated about twofold but may be four- or fivefold elevated in patients with alcoholic hepatitis. Serum GGT is commonly used as a screening test for alcohol abuse. However, GGT is an inducible enzyme that is elevated by many drugs and many disease states. Thus, the clinical sensitivity of GGT for alcohol consumption is satisfactory, but it is not a specific test of chronic alcohol abuse. Ethyl esters of fatty acids have also been proposed as markers of ethanol intake.[252A] Covalent protein adducts are also formed by the liver as a result of ethanol metabolism and lipid peroxidation.[328A]

Alcohol interferes with a number of glycoconjugation reactions, perhaps as the result of acetaldehyde inhibition of hepatic glycotransferases. The isoforms of transferrin have been studied as markers of alcohol consumption, as excessive ethanol consumption results in the appearance in serum

of isoforms that are carbohydrate deficient (CDT, also called hyposialyl- and asialyltransferrin).[29A,152A,175A,328B,463C,476A,479A] The use of CDT for detecting problem drinkers has been reviewed.[242B] It also has been suggested that combining markers such as CDT and GGT will increase the accuracy of identifiying problem drinkers.[83A,408B] Independent of liver function, an increased mean erythrocyte corpuscular volume, an indicator of dysfunctional production of red cells, has also been proposed as a marker of chronic ethanol consumption and is more specific than GGT.[479A]

PT may be prolonged and serum albumin decreased as the disease becomes more severe. Serum levels of procollagen type III correlate reasonably well with collagen synthesis and disease severity in chronic alcoholic liver disease. Nonspecific laboratory abnormalities reflecting the diffuse metabolic changes that occur with alcoholism include hyperuricemia, hyperlacticacidemia, hypertriglyceridemia, hypoglycemia, hyperglycemia, hypophosphatemia, hypomagnesemia, and macrocytosis. Liver biopsy is essential for determining disease severity and prognosis as well as to rule out treatable diseases such as chronic hepatitis and hemochromatosis.

The prognosis of alcoholic liver disease is better than that for other forms of liver disease, with only 10% to 15% developing cirrhosis and a much smaller fraction developing HCC.[351A] Both hepatitis B and hepatitis C appear to accelerate the course of alcoholic liver disease. The 5-y survival rate in patients with cirrhosis, jaundice, and ascites is 40% if the patient continues drinking and 60% if the patient abstains.[359A]

The primary treatment of alcoholic liver disease is abstinence from alcohol. However, new and promising approaches for drug treatment of the disease have resulted from a more extensive understanding of the neurobiological substrates of alcohol dependence, including adaptive changes in amino acid neurotransmitter systems, stimulation of dopamine and opioid peptide systems, and, possibly, changes in serotonergic activity.[27A,275A,275B] Previous studies have indicated that endogenous opioids are involved in the craving for alcohol[453A] and opioid antagonists such as naltrexone are being used to treat the disease.[73A,275A,374A,414A,453A] Currently, disulfiram, naltrexone, and acamprosate are currently the only treatments approved for the management of alcohol dependence.[275A,414A] Studies in animals have demonstrated that a diet enriched in vitamin E and saturated fatty acids reduces alcoholic liver injury by decreasing lipid peroxidation.[319A] Liver transplantation is the treatment of choice in end-stage liver disease. The results of transplantation in alcoholic liver disease are comparable to those with other forms of liver disease.[236A]

Cirrhosis

Cirrhosis, defined anatomically as diffuse fibrosis with nodular regeneration, represents the end stage of scar formation and regeneration in chronic liver injury. This response to injury occurs independently of the etiology and thus it is not possible, in most circumstances, to determine the cause of cirrhosis based on the histology. Classically, cirrhosis has been classified as (1) micronodular, (2) macronodular, or (3) mixed based on the histology and gross appearance of the liver. However, this is considered inadequate for etiological or prognostic purposes. Consequently, it is now more common to classify cirrhosis based on the presumed or known etiology. The common causes of cirrhosis and their therapies are listed in Table 47-7. Virtually all chronic liver diseases are known to lead to cirrhosis (see Figure 47-13), but most cases of cirrhosis occur as a result of chronic hepatitis.

TABLE 47-7 Causes and Treatment of Cirrhosis

Cause	Treatment
Viral	
Hepatitis B	Administration of α-interferon
Hepatitis C	Administration of α-interferon
Toxic	
Alcohol	Abstinence, liver transplantation
Methotraxol	Abstinence
Metabolic	
Hemochromatosis	Phlebotomy
Wilson's disease	Penicillamine
α_1-Antitrypsin deficiency	Gene therapy possible
Biliary	
Primary biliary cirrhosis	Ursodeoxycholic acid
Primary sclerosing cholangitis	Liver transplantation
Autoimmune hepatitis	Corticosteroids, azathioprine
Idiopathic	

In the early stages of transition from chronic hepatitis to cirrhosis, termed compensated cirrhosis, there may be no signs or symptoms of liver damage. Laboratory abnormalities usually appear before clinical findings such as ascites, gynecomastia, palmar erythema, and portal hypertension begin to develop. The earliest laboratory abnormalities to develop in cirrhosis are (1) fall in platelet count,[171,274] (2) increase in PT, (3) decrease in the albumin to globulin ratio to less than one,[274] and (4) increase in the AST/ALT activity ratio to greater than one.[171,274] Survival in those with compensated cirrhosis is good; 10-year survival rate in a large series was 90%.[145] As cirrhosis progresses, decompensation occurs. A variety of manifestations of portal hypertension may be present, as detailed earlier in the chapter. Jaundice is a late finding in decompensated cirrhosis. Once decompensation occurs, 10-year survival is only about 20%.[145] A variety

TABLE 47-8 Child-Pugh System for Classifying Severity of Cirrhosis

Feature	1 point	2 points	3 points
Encephalopathy	None	Grade 1-2	Grade 3-4
Ascites	None	Slight	Moderate-severe
Albumin (g/dL)	>3.5	2.8-3.5	<2.8
Prothrombin time (s prolonged)	<4	4-6	>6
Bilirubin (mg/dL)	<4	4-10	>10

Scoring: <7 points—Class A; 7-9 points—Class B; >9 points—Class C.

TABLE 47-9 The Hepatic Glycogen Storage Diseases

Type	Eponym	Enzyme Defect	Involved Tissues
0		Glycogen synthetase	Liver
I	von Gierke	Ia glucose-6-phosphatase Ib translocase for glucose 6-phosphatase Ic phosphate/pyrophosphate translocase	Liver, kidney, intestines
II	Pompe's	Lysosomal acid α-1,4 glucosidase	Most tissues
III	Cori	Amylo-1,6 glucosidase debranching enzyme	Liver, muscle, WBCs
IV	Anderson's	Amylo-1,4,1,6 trans glucosidase (branching enzyme)	Most tissue
VI	Hers'	Liver phosphorylase	Liver, WBCs
VII		Phosphorylase activation	Liver
IXa		Phosphorylase kinase	Liver, WBCs, RBCs

WBCs, White blood cells; *RBC*, red blood cells.

of staging systems have been used to predict prognosis in cirrhosis. For many years, the most common classification system was the Child-Pugh class system, summarized in Table 47-8. Currently, the MELD score [calculated as 3.8 + ln bilirubin (mg/dL) + 11.2 ln International Normalized Ratio + 9.6 ln creatinine (mg/dL) + 6.4 etiology score (0 if alcohol or obstruction, 1 for all other causes)] has been used to identify patients with advanced cirrhosis who may be candidates for liver transplantation; it appears superior to the Child-Pugh scoring system in predicting short-term survival.[57,61,155,387] Risk of death over 3 months is low in those with MELD scores below 10, intermediate in those with scores of 10 to 20, and high in those with scores above 20.[229]

Laboratory findings in cirrhosis reflect ongoing liver injury and decreased hepatic function. The most common laboratory findings in individuals with cirrhosis are summarized in Table 47-9. Activities of aminotransferases are variable in cirrhosis, and reflect activity of underlying necroinflammatory activity. If the cause of cirrhosis has been eliminated (as by abstinence from ethanol or successful treatment of viral hepatitis), aminotransferase activity is often within the reference interval. Persistence of elevation is a risk factor for development of HCC.[389] As described earlier, the ratio of AST/ALT activity is often greater than 1 in cirrhosis.[171,347,404,468] The mechanism for the change in ratio is not clear, but there appears to be a decrease in the production of ALT in cirrhotic individuals.[392] Increases in alpha fetoprotein (AFP) are common in cirrhotic patients, even in the absence of HCC.

Hepatic Glycogenoses

The glycogenoses are a group of disorders that are characterized by excessive and/or aberrant glycogen storage in various tissues. Most of these have deficient glucose production by the liver, leading to hypoglycemia. All are inherited by autosomal recessive transmission except for type IV, which is sex-linked. The hepatic glycogen storage diseases and their enzyme defects are listed in Table 47-9.

Most of these disorders are associated with growth retardation and hepatosplenomegaly. Mental development is usually normal. Hypoglycemia is a prominent feature in types I, III, and VI and needs to be treated with continuous glucose feeding of uncooked cornstarch, which results in a slow release of glucose.

The diagnosis is based on the demonstration of excess glycogen in the liver biopsy and in vitro identification of the abnormal enzyme or aberrant glycogen. Prognosis and treatment vary with each entity.

Cholestatic Liver Diseases

Cholestasis (stoppage or suppression of the flow of bile) is associated with retention of bile within the excretory system.

The term obstruction is often used inappropriately, since cholestasis can occur without mechanical obstruction to the biliary tract. Although intrahepatic cholestasis may be due to either functional or mechanical problems, extrahepatic cholestasis is always due to physical obstruction of the bile ducts by processes such as choledocholithiasis, biliary strictures, and tumors. The major cholestatic diseases are (1) mechanical obstruction of the bile ducts, (2) primary biliary cirrhosis (PBC), and (3) primary sclerosing cholangitis (PSC). Other cholestatic disorders include (1) post–bone marrow transplant cholangiopathy, (2) post–liver transplant cholangiopathy, (3) drug-induced cholestasis, (4) AIDS cholangiopathy, and (5) bilirubinostasis of acute illness. Cholestatic hepatitis, which has been discussed previously, may also cause cholestasis, but generally presents in a fashion closer to hepatitis.

The clinical consequences of prolonged cholestasis are related to the impaired biliary drainage. Deficiency of bile acids in the intestinal tract leads to malabsorption of fat and the fat soluble vitamins A, D, E, and K (see Chapters 30 and 49). Vitamin A malabsorption results in night blindness. Vitamin D malabsorption results in calcium and phosphate malabsorption, causing rickets in children and osteomalacia in adults. Vitamin K malabsorption results in deficiency of coagulation factors II, VII, IX, and X, leading to prolonged clotting times and bleeding. Lack of excretion of normal bile contents leads to their accumulation in plasma. Bile acid retention leads to increased bile acid concentrations in plasma. Although this has been historically associated with pruritus, it now appears that endogenous opioid-receptor analogues and increased serotonin are responsible.[225,226] Accumulation of cholesterol is associated with the development of an abnormal lipoprotein-X,[299,322] containing phospholipids, cholesterol, fragments of cell membrane (along with ALP),[60] and albumin; the lipid may deposit in connective tissue, producing xanthomas. Bilirubin retention leads to jaundice, dark urine, and pale stools. Increased bilirubin generally occurs only with complete obstruction and thus is more commonly seen with extrahepatic than intrahepatic cholestasis.

Laboratory features of cholestasis vary, depending on whether the process causes complete or partial impairment of biliary drainage. The common feature of all cholestatic disorders is an increase in plasma activities of canalicular enzymes, such as ALP and GGT. Because this process involves both increased synthesis of enzyme and release of enzyme from its membrane bound forms, there is generally a short lag period between the onset of cholestasis and the increase in plasma activities. In the early stages of an acute mechanical obstruction (especially from gallstones), there may be transient increases in plasma activities of liver cytosolic enzymes, such as AST and ALT. Plasma AST and ALT may exceed 400 IU/L, and in 1% to 2% of cases are more than 2000 IU/L. Even in the presence of continued obstruction, AST and ALT activity gradually decrease, and AST is typically within the reference interval within 8 to 10 days. Increases in total bilirubin typically occur only with complete extrahepatic obstruction, although they may be seen with extensive intrahepatic cholestasis. Increases in direct bilirubin are more commonly seen, and direct bilirubin has been reported to be the most sensitive functional test of the presence of cholestasis. In all forms of cholestasis, there is downregulation of the multidrug resistance transport protein 2 (MRP2), congenitally deficient in Dubin-Johnson syndrome.[436] Prolonged PT is the most commonly detected coagulation abnormality. It usually is corrected by administration of parenteral vitamin K. Increased cholesterol is a common finding in chronic cholestasis and along with increased canalicular enzymes is one of the most consistent features of cholestatic disorders. Lipoprotein-X will be included in LDL cholesterol in the Friedewald formula and in some direct LDL cholesterol methods.[150] Although lipoprotein-X is specific for cholestasis, it is not found in all individuals with cholestatic disorders.[413]

Mechanical Bile Duct Obstruction

The most common cause of cholestasis is biliary tract obstruction by space occupying lesions.[401] Extrahepatic bile duct obstruction occurs most commonly because of gallstones in the common bile duct or because of tumors in the head of the pancreas or duodenum. Other causes of extrahepatic obstruction include bile duct strictures, extrinsic compression of the bile ducts by enlarged lymph nodes, congenital biliary atresia, and PSC. Extrahepatic obstruction is commonly associated with jaundice, especially when obstruction is complete. Elevation in canalicular enzymes is common, but is not present in all cases[270]; marked increases (more than three times the upper reference limit) are more common with gallstones as a cause of obstruction.[458] Transient increases in aminotransferases are more common with choledocholithiasis than with other causes of extrahepatic obstruction.[218] Transient increases in CA 19-9 occur with bile duct obstruction[41]; this is an important consideration, as CA 19-9 is often used as a diagnostic test for pancreatic and bile duct carcinomas. A key feature of extrahepatic obstruction is dilation of more proximal and intrahepatic bile ducts, which can be visualized by imaging studies.[250]

Intrahepatic cholestasis caused by mechanical obstruction is also common, but is rarely associated with jaundice or with visibly dilated ducts on imaging studies, although it may be associated with increased direct bilirubin. Jaundice typically occurs only with lesions that are very large, or are located near the porta hepatis, where they may obstruct both hepatic ducts. Common causes of intrahepatic obstruction include (1) tumors (particularly metastases), (2) granulomatous diseases (such as sarcoidosis and tuberculosis), and (3) infiltrative processes (such as lymphoma, leukemia, and extramedullary hematopoiesis).

Primary Biliary Cirrhosis

PBC, or nonsuppurative destructive cholangitis, is an uncommon autoimmune disorder targeting intrahepatic

bile ducts. Its prevalence is approximately 2 to 8 per 100,000 population in the developed world, but it is much lower in developing areas. The median age at onset is 50 years, and the female to male ratio is about 6:1. There is an association in some populations with HLA class II antigen DR8. A family history of PBC is present in 1% to 4% of cases. In up to 80% of cases, it is associated with other autoimmune processes, most commonly Sjögren syndrome[325] and hypothyroidism (which often develops before onset of PBC).[100]

The pathogenesis of PBC is not well understood. However, it is known that the destruction of the bile duct is mediated by T cells in the presence of upregulation of HLA class I antigens on hepatocytes and HLA class II antigens on biliary epithelial cells.[168] Although the target antigens of the T cells have not been identified,[450] at least 95% of patients have antimitochondrial antibodies that react against the dihydrolipoamide acyltransferase component of the pyruvate decarboxylase complex.[449] Part of this complex is found on the apical surface of biliary epithelial cells, suggesting a role for this antigen as an immune target.[314] In individuals with coexisting Sjögren syndrome, the antigen is also expressed on the surface of salivary gland cells.[441]

PBC typically presents as an asymptomatic elevation of ALP, but may present with features of cholestasis or with fatigue. Metabolic bone disease and xanthomas are common complications of PBC.[192] Occasionally, autoantibodies are detected (usually because of the presence of another autoimmune disease or because of family history of PBC) before elevation of ALP.[300] Aminotransferase activities are increased in 50% of cases, but are more than twice the upper reference limit in only 20% of cases.[266] Increased bilirubin is a late finding and is important in predicting decompensation.[248] Antibodies to mitochondria or to the recombinant pyruvate decarboxylase complex appear similar in sensitivity, although the latter are more specific.[448] A liver biopsy is not required for diagnosis in most cases, but may be helpful in those with low titer antibodies or with greater than twofold increase in aminotransferase activity.[192]

The natural history of PBC is one of slow progression to portal hypertension, often without development of cirrhosis. Medical management of PBC consists of ursodeoxycholic acid, 13 to 15 mg/kg/day, which improves symptoms but appears to have no effect on long-term survival or need for liver transplantation.[345] Although a rare complication, the relative risk of developing HCC is significantly increased in individuals with PBC.[329] Liver transplantation is the only definitive treatment, but even then, PBC may recur in the transplanted organ.[148]

Primary Sclerosing Cholangitis

PSC is a chronic inflammatory disease of the biliary tree, most commonly affecting extrahepatic bile ducts; involvement of intrahepatic ducts, either with extrahepatic involvement or as an isolated finding, is also possible.[26,491] In contrast to PBC, PSC has a male predominance and a younger median age at onset of 30 years. In 70% of patients, PSC is associated with ulcerative colitis, which usually (but not always) precedes onset of PSC. This has led to speculation that bacterial antigens in portal blood might be involved in pathogenesis of PSC.[26] An autoimmune component is likely, as 97% of patients with PSC have one or more autoantibodies present in their plasma.[27] The prevalence of PSC is similar to that of PBC, but there are geographic differences in prevalence; it is most common in Northern Europe, where PSC is the most common indication for liver transplantation.[393] There is a markedly increased prevalence of HLA antigens B8 and DR3.[464]

The clinical presentation of PSC, like that of PBC, is typically an asymptomatic patient with elevated ALP concentrations found during routine laboratory screening. Symptoms are ultimately present in most patients with PSC; the most common are pruritus and intermittent abdominal pain, but fever may also be present.[340] Treatment, either medical or surgical, may improve laboratory tests and symptoms, but does not improve long-term survival.[257,293] Transplantation is the major treatment available for end-stage PSC and has a high rate of long-term survival. Although PSC recurs after transplantation in about 20% to 35% of cases, it does not appear to affect survival.[178,452] Transplantation also appears to increase the severity of underlying ulcerative colitis, when present.[134] The major cause of death in individuals with PSC is cholangiocarcinoma, which ultimately develops in up to one third of patients.[26,491] Transplantation in the presence of cholangiocarcinoma is associated with rapid development of metastatic disease and poor survival.[10] PSC also increases the likelihood of colon carcinoma in individuals with coexisting ulcerative colitis, although the risk is not affected by liver transplantation.[466]

At the time of diagnosis, most patients with PSC have elevated ALP and other canalicular enzymes; bilirubin is typically normal, although it may increase with acute exacerbations. The diagnosis of PSC is based on the typical radiographic appearance of beading and irregularity of the bile ducts.[453] Antineutrophil cytoplasmic antibodies (ANCA) are present in approximately 50% to 80% of patients but are not specific for PSC; they are also present in PBC and autoimmune hepatitis. Typically the antibodies have an atypical perinuclear pattern, being located near the nucleus both in formalin and methanol fixed preparations. Antigens include lactoferrin, bactericidal/permeability increasing protein, and cathepsin G.[315,375,376]

Drug-Induced Cholestasis

Drugs are a common cause of cholestasis, causing about 15% of cases.[497,498] Drug reactions are especially common in older individuals, where up to 50% of individuals have increased enzymes because of medications.[497] Drugs can cause a cholestatic picture by two major mechanisms.[495,498] In some cases, only conjugated bilirubin is increased, whereas canalicular enzymes are not elevated. This picture, often seen

with estrogen and anabolic steroids, appears because of inhibition of production of MRP2,[436] as discussed earlier in other cholestatic disorders. More commonly, drugs induce a cholestatic hepatitis, as discussed earlier.

Gallstones

Gallstones are solid formations in the gallbladder that are composed of cholesterol and bile salts. Although they vary in chemical composition, they generally contain a mixture of cholesterol, bilirubin, calcium, and mucoproteins. In the United States, 70% to 85% of all gallstones are predominantly cholesterol and more than 10% of the adult population is affected.

There are three major types of gallstones: (1) cholesterol gallstones, (2) pigmented gallstones, and, most common, (3) mixed gallstones. These stones form whenever bile is supersaturated with cholesterol or unconjugated bilirubin. Most gallstones are mixed cholesterol and pigment stones. For these stones or cholesterol gallstones to form, bile must be supersaturated with cholesterol. Whenever there is an increase in cholesterol or a decrease in bile acids or lecithin, bile becomes lithogenic (prone to stone formation), and cholesterol may precipitate. Factors that predispose to cholesterol hypersecretion are obesity, aging, certain drugs such as clofibrate and nicotine, and certain hormones such as estrogen. Factors that decrease bile acid secretion are terminal ileal disease and cholestatic diseases, such as PBC, PSC, and cystic fibrosis. Genetic factors also appear to be involved. Within racial groups, women are more frequently affected than men. Diet may play a role because it appears that people who ingest diets high in polyunsaturated fats have a higher incidence, whereas those with a diet high in fiber have a decreased incidence.

Pigmented gallstones are associated with conditions in which the bilirubin load is increased, such as hemolytic anemia, or when bilirubin becomes insoluble (i.e., deconjugated), such as occurs with cholestasis or chronic biliary infections.

Rare Causes of Cholestasis

A number of other disorders are associated with cholestasis. Because they occur in specific settings, they are often suggested by the clinical picture. Laboratory tests are of little help in establishing the correct diagnosis.

Cholestasis may develop following bone marrow transplantation because of a variety of factors. Acute graft-versus-host disease (GVHD) is a consequence of the infusion of allogeneic immunocompetent T-lymphoid cells into an immunocompromised host that cannot reject these cells.[210] The periductular epithelial cells are the primary targets of injury in both acute and chronic GVHD.[46,386] Clinical features of GVHD include skin rash, intestinal symptoms (nausea, vomiting, diarrhea, and abdominal pain), and cholestasis. The histological appearance is characteristic, but a liver biopsy is somewhat hazardous in these patients, and thus most patients' disorders are diagnosed on clinical grounds.

Although acute liver transplant rejection is associated with necroinflammatory changes and increases in aminotransferases, chronic rejection is often associated with cholestasis. The primary targets of immunologic injury are bile ductules and blood vessels.[115] Because of cholestasis, plasma bile acids are often increased early in the process of rejection.[219] Increased numbers of canalicular membranes are often the first evidence of rejection.[115] Although eosinophilia is common in rejection,[319] it is also a common finding in drug-induced cholestasis, and is thus not helpful in the differential diagnosis.

AIDS cholangiopathies are caused by organisms not previously known to infect the biliary tree; they have become less common with reduction in the frequency of immunosuppression because of combination antiretroviral treatment. *Cryptosporidium* is the most common organism. *Microsporidium,* cytomegalovirus, *Mycobacterium avium* complex, and *Cyclospora* have also been identified. The clinical presentation usually includes abdominal pain, diarrhea, and cholestasis manifested by threefold to tenfold elevations in plasma ALP, mild elevations in aminotransferases, and rarely jaundice. Papillary stenosis at the ampulla of Vater is present in patients with pain, and the bile ducts have features of PSC. Cholangiography is needed for the diagnosis but is only indicated in patients with pain. Brushings and biopsies at the time of cholangiography will establish the diagnosis. Treatment is primarily endoscopic. Sphincterotomy will give pain relief in approximately 70% of patients.

Hepatic Tumors

The liver is host to a wide variety of both benign and malignant primary tumors. It is also the second most common site of metastases; metastatic tumors account for 90% to 95% of all hepatic malignancies. The primary tumors may arise from many cell lines in the liver but most commonly from parenchymal and biliary epithelial cells and mesenchymal cells (Table 47-10). The two most important primary liver tumors are HCC and cholangiocarcinoma.

Hepatocellular Carcinoma

HCC is the fifth most common cancer worldwide and a leading cause of cancer death. There are wide geographic and ethnic variations in the incidence, suggesting that both host and environmental factors are involved in its etiology. For example, approximately 75% of HCC occur in Asia, with an annual incidence of HCC in China of approximately 30 cases per 100,000 males. In contrast, the average annual incidence is less than 5 cases per 100,000 males in North America. Worldwide, the incidence is twofold to threefold higher among men than it is among women.[56] The incidence of HCC has been increasing, not only in North America,[137] but in the rest of the world, thought to be caused by the increasing frequency of cirrhosis caused by HCV.[136] Although cir-

rhosis is present in most patients with HCC, it is absent in about 25% to 30% of cases, often in association with HBV.[59,487] More importantly the presence of cirrhosis had been recognized before diagnosis of HCC in only about one third of cases.[483,488] There are wide variations in the incidence of HCC with different etiologies of cirrhosis. For example, HCC occurs commonly in cirrhosis caused by alcohol abuse, hemochromatosis, AAT deficiency, HBV, and HCV, but is rare in that caused by autoimmune hepatitis and Wilson's disease.

In most parts of the world, the major risk factors for development of HCC are infection with HBV or HCV. In Asia, Africa, and Alaska, the major risk factor is HBV infection. The presence of HBsAg and HBeAg is associated with a relative risk of HCC of 60, whereas the presence of HBsAg with negative HBeAg was associated with a relative risk of 10.[477] It is important to note that the frequency of HCC has been reduced significantly with prevention of chronic HBV by immunization.[82,254] Once cirrhosis has developed, the rate of development of HCC is about 1.5% to 5% per year in both HBV and HCV[146,147]; the relative risk of HCC doubles in those co-infected with both viruses.[144] The mechanism of increased risk in HBV is thought to be related to integration of HBV DNA into the host genome, possibly caused by the action of the HBV X gene, which may block the activity of p53.[151,444] The mechanism of increased risk in HCC in HCV has not been identified, but may be related to ongoing injury. The risk of HCC is higher in those with cirrhosis who have elevated aminotransferases than in those with normal ALT.[191,389] Interferon, which reduces inflammation, has been found to lower the risk of HCC in HCV, both as a primary tumor[54,232,425] and as recurrences following resection of a first HCC.[211,244,407]

Aflatoxin, a product of *Aspergillus flavus* contamination of grain, has been linked to risk of HCC; although it is harmless, it is metabolized to aflatoxin 8,9-epoxide. This reactive intermediate binds to guanosine bases in DNA, leading to mutagenesis. If the formed adduct is not repaired, G to T transversion occurs in codon 249 of the *p53* gene, causing an inactivating mutation.[368] Under normal circumstances, the mutagenic aflatoxin 8,9-epoxide is rendered harmless by glutathione-S-transferase, which converts it to a glutathione conjugate, which in turn is metabolized to 1,2-dihydrodiol by epoxide hydrolase.[264] However, both detoxifying enzymes are polymorphic in humans and the mutant forms are less active. Patients with HCC are more likely to have the mutant forms of epoxide hydrolase and glutathione-S-transferase, which allows accumulation of the epoxide.[291]

The clinical presentation of HCC is variable, but usually does not occur until late in the course of disease, when the tumor is large and resection is impossible. In some cases, acute decompensation occurs in a patient with cirrhosis, but clinical presentation may include detection of a right upper quadrant mass, shock because of hemorrhage into the peritoneal cavity, or right upper quadrant pain.[119] Nonspecific signs and symptoms, such as fever, malaise, anorexia, and anemia are common, and jaundice may occur with central tumors that obstruct biliary drainage. In a small number of cases, paraneoplastic features, such as hypoglycemia, hypercalcemia (due to parathyroid hormone–related peptide [PTHrP] production) or erythrocytosis (due to erythropoietin) may be the initial presenting findings, and such paraneoplastic findings occur in up to 20% of cases, usually associated with poor prognosis.[234,275] Laboratory findings include those of cirrhosis and cholestasis, and (except for tumor markers discussed below), are nonspecific.

Because treatment is usually not possible in individuals with clinically diagnosed HCC, there has been much interest in screening high risk individuals. Currently, most professional societies have not advocated screening for HCC in Europe or North America,[327] although most practicing hepatologists perform screening in patients with cirrhosis, especially that caused by viral hepatitis.[79] Although data from some areas have suggested that screening is effective in detecting small, treatable tumors, other data have not been as supportive.

The most common screening programs have used either plasma tumor marker concentrations or tumor markers plus imaging studies. Ultrasound is typically used as the imaging modality for screening because of its low cost. The tumor marker most widely used for screening purposes is AFP; it is typically quantified using assays that measure its total

TABLE 47-10 Classification of Hepatic Tumors

Benign	Malignant
Epithelial	
Adenoma	Hepatocellular carcinoma
Bile duct adenoma	Cholangiocarcinoma
Cystadenoma	Cystadenocarcinoma
Carcinoid	Squamous carcinoma
Focal nodular hyperplasia	
Diffuse nodular hyperplasia	
Mesenchymal Tumors	
Cavernous hemangioma	Hemangiosarcoma
Fibroma	Fibrosarcoma
Leiomyoma	Leiomyosarcoma
Hematoma	Hepatoblastoma
Metastatic Tumors (Most Common Sources)

Bronchogenic	

concentration. As discussed in Chapter 54, there also are modified forms of AFP that are more specific for tumors, particularly the L3 isoform recognized by lens culinaris (lentil) lectin. Total AFP has been the most widely used tumor marker; although it appears to be relatively sensitive, elevation of AFP is common in individuals with chronic hepatitis and cirrhosis, the group at highest risk for HCC. In our experience, AFP above the upper reference limit has a positive predictive value of only 16% for HCC. Use of higher cutoff values than the upper reference limit improves clinical specificity of total AFP, at the expense of clinical sensitivity. Fewer data exist for the L3 isoform of AFP, but specificity and positive predictive value are significantly improved.[406,424] An L3 isoform more than 15% of total AFP may be associated with more aggressive and less well differentiated tumors.[240,338] Des-γ-carboxy prothrombin (DCP)—also called PIVKA-2 (factor II protein induced by vitamin K antagonists)—is the inactive form of prothrombin found in individuals taking warfarin or other vitamin K antagonists. It was first found to be increased in HCC in 1984,[262] but was not widely used until the early 1990s. Initial studies found that DCP was increased in some patients who did not have elevated AFP, but was insensitive to small HCC that might be curable.[118,162] Pretreatment with vitamin K, to eliminate other causes of increased DCP, improves specificity further.[383] More recently, DCP immunoassays with lowered detection limits have been developed and have shown increased clinical sensitivity for small HCC.[213,320] DCP is best used as an adjunct to AFP, since tumors often produce one or the other tumor marker.[28]

The treatment of HCC is dependent on the extent of the tumor. Small tumors are often treated by transplantation, which has a low rate of recurrent tumor.[193] Local techniques, such as ethanol injection, chemoembolization, and use of radio frequency ablation, are increasingly used either pretransplant or instead of transplantation.[78,173,260] Larger tumors are generally not resectable, but may be treated by chemoembolization if a single feeding vessel is identified. A novel approach to identifying micrometastases has recently been introduced using reverse transcription PCR to amplify mRNA for AFP to detect recurrence or metastasis.[470]

Tumors of the Gallbladder and Bile Ducts

Benign lesions such as papillomas or adenomas may be seen as an incidental finding at cholecystectomy; malignant disease of the gallbladder is uncommon. Cholelithiasis may be an etiological factor, as 85% of gallbladder carcinomas occur in patients with gallstones. However, fewer than 1% of patients with gallstones develop carcinoma. It has been suggested that a calcified gallbladder is especially prone to malignant transformation. Various pathological forms exist, including papillary adenocarcinoma, squamous cell carcinoma, and anaplastic tumors. These tumors usually arise in the neck of the gallbladder and spread rapidly, causing obstruction and cholestasis. Physical examination reveals a hard, tender mass in the gallbladder fossa. These lesions are particularly difficult to treat and the majority of cases are inoperable at the time of diagnosis.

Cholangiocarcinoma, or primary carcinoma of the bile ducts, can arise at any point in the biliary tree, including the small intrahepatic bile duct radicals. This lesion is typically associated with underlying liver disease, such as (1) PSC, (2) congenital cystic lesions, or (3) chronic infestation with *Clonorchis sinensis*. The clinical picture presentation is that of cholestasis, including jaundice, dark urine, tan-colored stool, and pruritus. Differentiation from other cholestatic diseases is made by visualizing the biliary tree.

DIAGNOSTIC STRATEGY

Liver function tests are useful in (1) detecting, (2) diagnosing, (3) evaluating severity, (4) monitoring therapy, and (5) assessing the prognosis of the liver disease and dysfunction. They are also useful in directing further diagnostic workup. The array of tests useful for these purposes (Table 47-11) includes measurement in plasma of total bilirubin, protein, and albumin concentrations and the activity of enzymes such as the aminotransferases (AST and ALT), ALP, lactate dehydrogenase (LD), and GGT. By using a combination of these tests, it is possible to categorize broad types of liver disease, which can then be more accurately diagnosed through disease-specific tests. An algorithm for that process is presented in Figure 47-17.

TABLE 47-11 Tests of Hepatic Function

Test	Utility
Bilirubin	Diagnosing jaundice, modest correlation with severity
Alkaline phosphatase (ALP)	Diagnosing disorders of metabolism and disorders of the newborn
Bilirubin fractionation	Diagnosing cholestasis and space-occupying lesions
Aspartate aminotransferase (AST)	Sensitive test of hepatocellular disease; AST > ALT in alcoholic disease
Alanine aminotransferase (ALT)	Sensitive and more specific test of hepatocellular disease
Albumin	Indicator of chronicity and severity
Prothrombin time (PT)	Indicator of severity of cholestasis

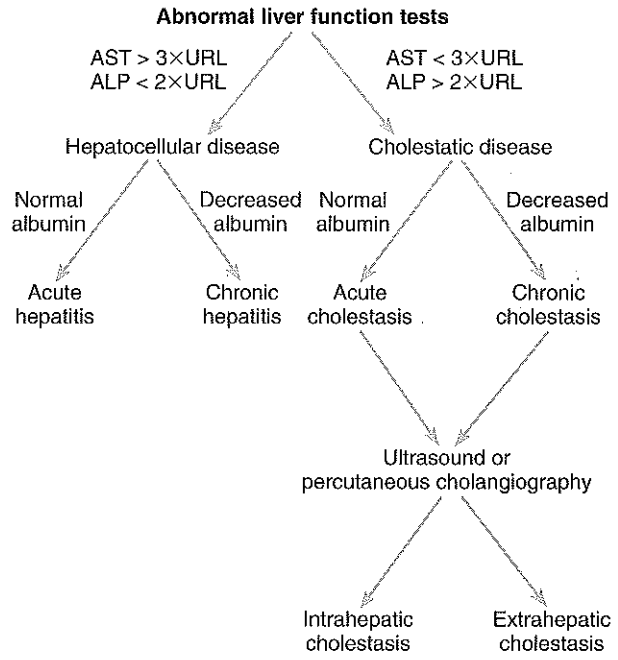

Figure 47-17 Algorithm for using abnormal liver function tests to classify and diagnose various types of liver disease. *ALP,* Alkaline phosphatase; *AST,* aspartate aminotransferase; *URL,* upper reference limit.

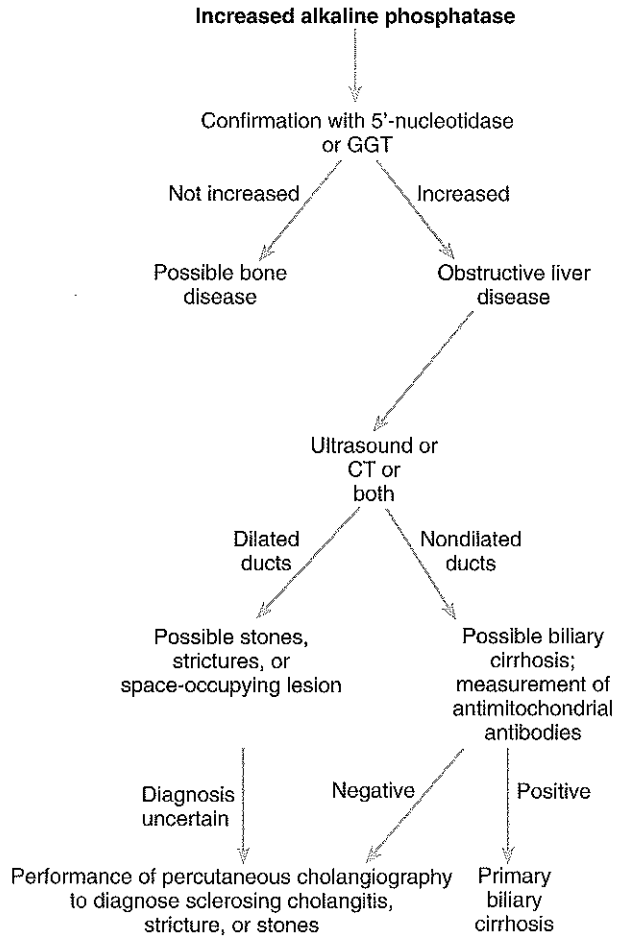

Figure 47-18 Algorithm for using elevated activities of serum alkaline phosphatase in the diagnosis of liver disease in adults.

Plasma Enzymes

In practice, the plasma aminotransferases and ALP are the most useful tests as they allow differentiation of hepatocellular disease from cholestatic disease. The importance of this distinction cannot be overstated: failure to recognize cholestatic disease caused by extrahepatic biliary obstruction will result in liver failure if the obstruction is not quickly corrected. It is also important to recognize that there may be a gray zone of mixed hepatocellular and cholestatic disease where the tests do not distinguish one disease from the other. In this case, it is wise to assume that the problem is cholestatic and rule out biliary obstruction.

Patients are occasionally seen with isolated elevations in ALP or aminotransferase enzyme activities. In practice, an isolated increase in ALP activity is difficult to interpret. In children, *benign transient hyperphosphatasemia* should always be considered. In adults, it is necessary to first confirm that the ALP is of hepatobiliary origin. This can be done by isoenzyme fractionation (see Chapter 21) or by measuring another phosphodiesterase enzyme such as 5′ nucleotidase (Figure 47-18) or by measuring GGT activities, which tend to parallel activities of ALP in cholestasis. The most important aspect of the workup is to rule out space-occupying lesions by visualizing the liver with CT, and biliary tract disease by visualizing the biliary tree with ultrasound or cholangiography.

Elevated plasma activities of AST and ALT are common in many disorders (see Chapter 21). To determine if this elevation is liver related, administration of all drugs and alcohol intake (especially if AST is higher than ALT) should be discontinued. If the elevation persists, ultrasound (looking for nonalcoholic fatty liver) and hepatitis B and C serology should be performed. More than 50% of isolated enzyme elevations of liver origin will be caused by these disorders. A liver biopsy is often needed to make a more specific diagnosis. There is no reliable test other than a liver biopsy to detect fibrosis. Plasma procollagen type III peptide has been used, but correlates better with disease activity than fibrosis.

Plasma Albumin

Plasma albumin measurements are useful in assessing the chronicity and severity of liver disease. For example, the plasma albumin concentration is decreased in chronic liver disease. However, its utility for this purpose is somewhat limited, as the plasma albumin concentration is also decreased in severe acute liver disease. Serial measurements of plasma albumin can be used to assess the severity of liver disease.

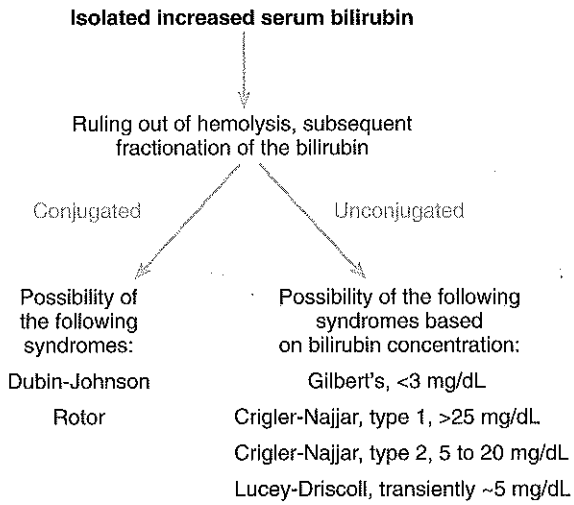

Figure 47-19 Algorithm for differentiating the familial causes of hyperbilirubinemia.

Prothrombin Time

Serial PT measurements also can be used to differentiate between cholestasis and severe hepatocellular disease. In practice, PT should be measured again after vitamin K injection, because cholestasis will cause a decrease in PT because of malabsorption of vitamin K. The patient has cholestasis if the PT corrects after vitamin K replacement (10 mg subcutaneously or intramuscularly, followed by PT measurement 4 hours later). With time, if the PT does not return to normal, the patient has severe hepatocellular disease.

Plasma Bilirubin

Serial measurement of bilirubin is helpful in measuring the severity of liver disease. Bilirubin fractionation is helpful only in jaundice of the newborn or in isolated elevations of bilirubin in the absence of other liver test abnormalities that would indicate an inherited disorder of bilirubin metabolism.

Patients are occasionally seen with isolated elevations in bilirubin concentration. In most cases, this is due to inherited disorders of bilirubin metabolism, familial hyperbilirubinemia, or hemolysis. It is not difficult to distinguish hemolysis severe enough to cause hyperbilirubinemia, because the patient with hemolysis will have many other disease manifestations. An algorithm for differentiating the familial causes of hyperbilirubinemia is presented in Figure 47-19.

CHAPTER 48

Gastric, Pancreatic, and Intestinal Function*

Peter G. Hill, Ph.D., C.Chem., F.R.S.C., F.R.C.Path.

The stomach, intestinal tract, and pancreas are closely related, both anatomically and functionally, and symptoms, such as diarrhea or malabsorption, may be associated with diseases or disorders of any of these organs. It is therefore appropriate to discuss them together. Advances in imaging techniques and improvements in endoscopic procedures have led to enormous changes in the investigation of gastrointestinal (GI) and pancreatic function so that many laboratory tests, once considered important, have now been superseded.

In this chapter, the anatomy and physiology of the GI tract, and the normal processes of digestion and absorption, are briefly reviewed. Disorders of the stomach, pancreas, and intestine associated with malabsorption or diarrhea, in which the laboratory can play a role in diagnosis and monitoring, are discussed. The chapter concludes with an overview of GI regulatory peptides and neuroendocrine tumors in which GI symptoms are prominent, and with two sections presenting more integrated approaches to the problems of investigating malabsorption and diarrhea.

INTRODUCTION TO ANATOMY AND PHYSIOLOGY OF THE GASTROINTESTINAL TRACT[170]

The major organs of the GI tract include the stomach, the small and large intestines, the pancreas, and the gallbladder, all of which are involved in the digestive processes that commence with the ingestion of food and water and culminate in the excretion of feces.

*The author gratefully acknowledges the original contributions of Drs. A. Ralph Henderson and Alan D. Rinker, upon which a portion of this chapter is based.

ANATOMY

The GI tract is a 10-meter-long tube beginning with the mouth and ending with the anus. The esophagus is about 25 cm in length and is a muscular tube connecting the pharynx to the stomach. For this chapter, the key organs are the stomach, intestines, and pancreas.

Stomach[147]

The stomach consists of three major zones: the cardiac zone, the body, and the pyloric zone (Figure 48-1). The upper cardiac zone, which includes the fundus, contains mucus-secreting surface epithelial cells, which also secrete group II pepsinogens, and several types of endocrine secreting cells. The body of the stomach contains cells or cell groups of many different types: (1) surface epithelial cells, which secrete mucus; (2) parietal (oxyntic) cells, which secrete hydrochloric acid and intrinsic factor; (3) the chief, zymogen, or peptic cells, which secrete groups I and II pepsinogens; (4) enterochromaffin cells, which secrete serotonin; and (5) several types of endocrine secreting cells. The pyloric zone is subdivided into the antrum (which is approximately the distal third of the stomach), the pyloric canal, and the sphincter. The cells of the pyloric zone secrete mucus, group II pepsinogens, serotonin, gastrin, and several other hormones but no hydrochloric acid.

Small Intestine

In the stomach, food is converted into a semi-fluid, homogeneous, gruel-like material (chyme) that passes through the pyloric sphincter into the small intestine. The small intestine consists of three parts: the duodenum, jejunum, and ileum. In the adult human, the small intestine is approximately 2 to 3 m long and decreases in cross-section as it proceeds dis-

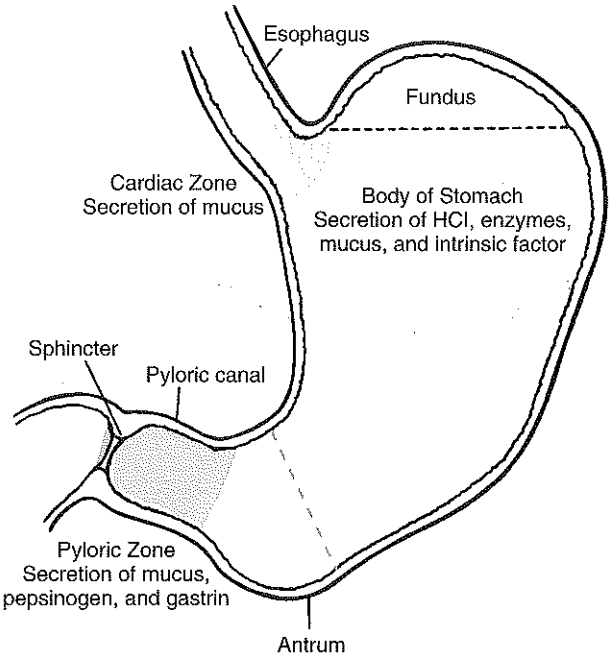

Figure 48-1 Schematic drawing of the stomach, with major zones.

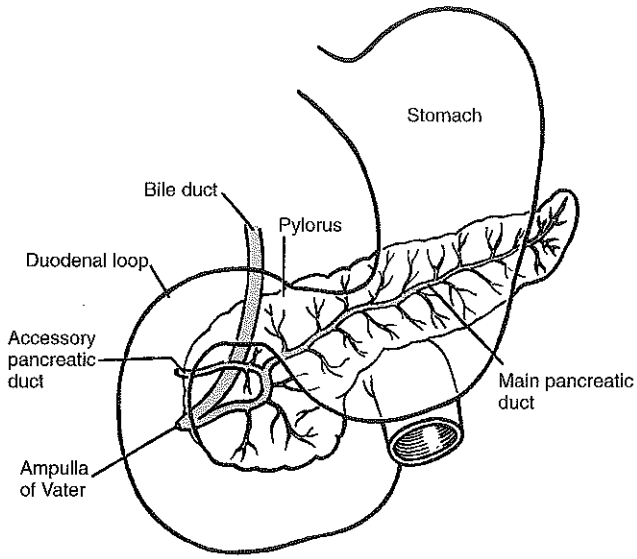

Figure 48-2 Cross-section through the pancreas.

tally. The duodenum is about 25 cm long and is the shortest and widest part of the small intestine. The jejunum and ileum comprise the remainder of the small intestine. There is no clear demarcation, but the ileum is the distal three fifths.

The wall of the small intestine consists of four layers: mucous, submucous, muscular, and serous. The internal surface of the upper small intestine contains valvulae conniventes; these are valve-like circular folds that project 3 to 10 mm into the lumen of the intestine. Covering the entire mucous surface of the small intestine are very small (1 mm) finger-like projections (villi), giving it a "velvety" appearance. The luminal surface (brush border) of each epithelial cell consists of some 600 microvilli projecting about 1 μm from the cell. The folds, villi, and microvilli together present an absorptive surface some 600 times greater than would be inferred from the length and diameter of this portion of the gut. The absorptive surface area of the small intestine is estimated to be about 250 m^2,[73] which is comparable to the area of a doubles tennis court.

Large Intestine

The large intestine is about 1.5 m in length, extending from the ileum to the anus, and includes the cecum, appendix, colon, rectum, and anal canal. The cecum is a blind pouch that begins the large intestine; it is connected to the terminal ileum via the ileocecal sphincter. The appendix is a "worm-shaped" tube connected to the blind end of the cecum. The colon is about 1 m long and is divided into the ascending, transverse, descending, and sigmoid sections. The sigmoid colon connects to the rectum, which is approximately 12 cm long. The rectum in turn connects to the anal canal, the terminal end of the large intestine.

Pancreas

The pancreas is 12 to 15 cm in length and lies across the posterior wall of the abdominal cavity. The head is located in the duodenal curve; the body and tail are directed toward the left, extending to the spleen (Figure 48-2). Pancreatic digestive enzymes, in bicarbonate-rich juice, enter the duodenum through the ampulla of Vater and the sphincter of Oddi and mix with the food bolus as it passes through the small bowel.

Phases of Digestion

The process of digestion can be conveniently subdivided into the neurogenic, gastric, and intestinal phases.

Neurogenic Phase

The neurogenic or cephalic phase is initiated by the intake of food into the mouth; the sight, smell, and taste of food stimulate the cerebral cortex and subsequently the vagal nuclei. The process is chemically mediated by acetylcholine from postganglionic parasympathetic nerve endings, which acts on gastric parietal cells. The vagus also stimulates gastric chief and parietal (oxyntic) cells to secrete pepsinogen and hydrochloric acid. (Cutting of the vagus nerve [vagotomy] decreases the volume and acidity of gastric secretion.)

The mechanism of acid secretion is still widely debated; there is, however, significant agreement that acetylcholine, histamine, and gastrin act through their respective neurocrine, paracrine, and endocrine pathways to stimulate the parietal cells, and that specific parietal cell receptors to these transmitters exist. Also, there are potentiating interactions between the mentioned secretagogues that probably occur at the parietal cell itself. Histamine has a role as a mediator or a potentiator of the actions of other secretagogues. Admin-

istration of histamine markedly increases the secretion provoked by pentagastrin or by cholinergic agonists. Histamine H_2-receptor antagonists inhibit acid secretion provoked by most types of stimulation, confirming the important role of histamine in acid secretion.

The parietal cell is transformed morphologically when acid secretion is stimulated. The tubulovesicular membranes, prominent in the resting cell, diminish, whereas there is a marked increase in the apical plasma membrane (the secretory surface of the cell) together with the appearance of long apical microvilli.

Cimetidine (Tagamet) and other H_2-receptor antagonists (such as ranitidine [Zantac] and famotidine [Pepcid]) block both the morphological transformation of the parietal cell and H^+ secretion. Proton pump inhibitors (PPIs) have a different mechanism of action. Omeprazole (a PPI) is taken up by the parietal cell and converted to an active metabolite that inactivates the parietal H^+, K^+-ATPase. Hydrogen ion secretion is inhibited until new ATPase is synthesized—a process that requires at least 24 hours.

The secretion of H^+ against a million-fold concentration gradient requires energy from the cell, and this process is coupled to H^+, K^+-ATPase. Histamine-stimulated acid secretion involves cyclic adenosine monophosphate (cAMP); cholinergic stimulation is not associated with increases in intracellular cAMP in isolated parietal cells, and this process may be mediated by changes in permeability of the cell's plasma membrane to Ca^{2+}. The latter activates a chain of events that alters the cell function in various ways. In addition to the previously mentioned mechanisms, vagal fibers to the pyloric glandular mucosa cause the release of gastrin, which also stimulates hydrochloric acid and pepsinogen secretion.

Other agents inhibiting acid secretion include somatostatin, prostaglandins, gastric inhibitory polypeptide (GIP), secretin, glucagon, vasoactive intestinal polypeptide (VIP), neurotensin, calcitonin gene-related peptide, corticotrophin-releasing factor, thyrotropin-releasing hormone, peptide YY, dopamine, and serotonin. Acid secretion is decreased in the presence of decreased amounts of circulating pituitary, adrenal, thyroid, and parathyroid hormones. Pituitary hormones are apparently essential for the maintenance of the structural integrity of the gastric mucosa and necessary for secretory function; human growth hormone may be necessary for the growth of the gastric mucosa.

Gastric Phase

When food enters the stomach, the resulting distention initiates the gastric phase of digestion, mediated by local and vagal reflexes. Hydrochloric acid release is caused by (1) direct vagal stimulation of the parietal cells; (2) local distention of the antrum and vagal stimulation of antral cells to secrete gastrin, which causes hydrochloric acid release from parietal cells; and (3) release of gastrin, stimulated by the near neutralization (pH 5-7) of gastric hydrochloric acid by ingested food entering the pyloric zone. Gastrin also stimulates antral motility, secretion of pepsinogens and of pancreatic fluid rich in enzymes, and release of a number of GI hormones (secretin, insulin, acetylcholine, somatostatin, and pancreatic polypeptide; for further information on GI hormones, see the later section of this chapter on GI Regulatory Peptides.). As a result of the acid environment, pepsinogen is rapidly converted to the active proteolytic enzyme pepsin. Food is mixed by contractions of the stomach and partially degraded by the chemical secretions of the stomach into chyme. The pylorus plays a role in emptying chyme into the duodenum by virtue of its strong musculature.

Intestinal Phase

The intestinal phase of digestion begins when the weakly acidic digestive products of proteins and lipids enter the duodenum. Many GI hormones and other regulatory peptides are released by both neural and local stimulation and act within the GI tract to regulate digestion and absorption. These are described in more detail in the section on GI Regulatory Peptides. Digestion, absorption, and storage functions are stimulated or inhibited by different hormones, creating an intricate hormonal control system that regulates the action of intestinal hormones and provides for secretion of bile acids, bicarbonate, and numerous enzymes involved in the digestion of food. In this system, the intestinal hormones secretin and VIP, for example, inhibit gastrin release and decrease the secretion of hydrochloric acid and pepsinogen; cholecystokinin (CCK; see discussion later in this chapter) binds to gastrin receptors and thus also decreases hydrochloric acid secretion. Somatostatin inhibits gastrin, secretin, CCK, and other hormones.

During the intestinal phase, carbohydrates, proteins, and fats are broken down and absorbed as described in the next section. Most nutrients, including vitamins and minerals, have been absorbed by the time the food passes from the jejunum and ileum into the large bowel. In the large intestine, water is actively absorbed, electrolyte balance is regulated, and bacterial actions take place. These processes result in the formation of feces.

PROCESSES OF DIGESTION AND ABSORPTION[52]

The total quantity of fluid absorbed each day by the gut is estimated to be about 9 L, which is composed of 2 L oral intake, 1.5 L saliva, 2.5 L gastric juice, 0.5 L bile, 1.5 L pancreatic juice, and 1 L intestinal secretions. More than 90% of this fluid is absorbed in the small intestine. The maximal absorptive capacity for fluid is probably at least 20 L. Several hundred grams of carbohydrates, about 100 g of fat, and 50 to 100 g of amino acids are absorbed daily in the small gut, but maximal absorptive capacity is believed to be at least 10 times greater. This considerable reserve capacity may compensate for mild to moderate degrees of dysfunction induced by disease processes, at least in the early phases. The efficiency of absorption is due to the unique features of the

absorptive surface of the bowel and the relationship of the epithelial cells to the underlying rich vascular plexus and the lymphatic vessels.

Digestion of ingested food takes place both within the lumen of the small intestine and at the mucosal (brush border) surface. Defects of digestion may occur at one or more stages in the process. The terms maldigestion and malabsorption refer to different functional abnormalities. Maldigestion is a dysfunction of the digestive process that may occur at various sites in the GI tract. For example, hypoacidity in the stomach will reduce peptic digestion of protein; hyperacidity of the duodenum (e.g., due to overproduction of gastrin by tumor in the Zollinger-Ellison syndrome) can inactivate pancreatic enzymes; loss of brush border enzymes in the small intestine, because of any of a variety of processes, can prevent oligosaccharides and disaccharides from being further hydrolyzed; pancreatic insufficiency will reduce intraluminal enzyme activity in the small gut, causing maldigestion of fats and proteins. By contrast, malabsorption is strictly a dysfunction of the absorptive process by the small gut caused by a loss of absorptive epithelial cells caused, for example, by gluten, inflammation, infection, surgical resection, and infiltrations. A number of transport defects also lead to malabsorption of specific substances (e.g., glucose-galactose malabsorption or zinc deficiency in the congenital disorder acrodermatitis enteropathica). In clinical practice, however, the term malabsorption is often used to encompass all aspects of impaired digestion and absorption. As Figure 48-3 shows, absorption of the different nutrients proceeds at different rates and at different sites within the small bowel.

In the following three sections, the digestion and absorption of fats, carbohydrates, and proteins will be discussed separately. It must be remembered, however, that there is a complex interplay among nutrients, regulatory peptides, enzymes, gallbladder and pancreatic function, and bowel motility leading to an integrated absorptive process commencing with the ingestion of food and culminating in the excretion of feces.

Digestion and Absorption of Carbohydrates

After the action of salivary and pancreatic α-amylases on dietary starch and glycogen, the carbohydrate content of the small intestine consists of newly formed maltose; ingested monosaccharides; dietary disaccharides, such as lactose, sucrose, maltose, and trehalose; oligosaccharides, such as dextrins and maltotriose; and indigestible oligosaccharides and polysaccharides, such as cellulose, agar, and other oligosaccharide dietary fibers.

The brush border enzymes with disaccharidase and oligosaccharidase activity are listed in Table 48-1. The sucrase-isomaltase complex comprises most of the sucrase, isomaltase, and maltase (80%) activity of the small intestine. It hydrolyzes sucrose to its constituent monosaccharides, cleaves glucose from α-limit dextrins with 1,6 bonds, and hydrolyzes maltose. The activity of the complex is fourfold to fivefold greater in the jejunum than in the ileum. Changes in diet have a marked effect on the expression of the complex; starvation leads to a rapid decline in activity, which is rapidly restored on refeeding. All small intestinal saccharidases may decrease with infection or inflammation of the small bowel to the extent that carbohydrate malabsorption

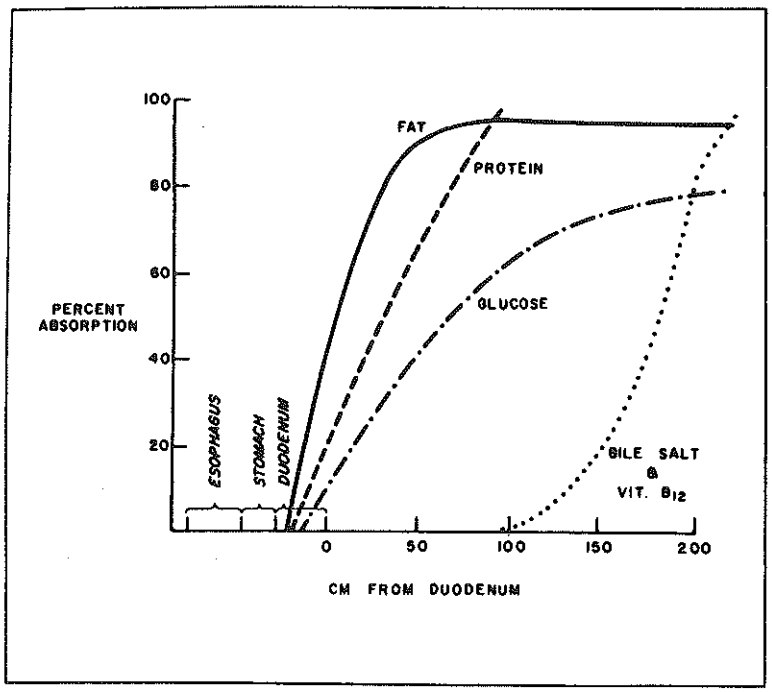

Figure 48-3 The location of small intestinal absorption. *(Modified from Morris JA, Selivanov V, Sheldon GF. Nutritional management of patients with malabsorption syndrome. Clin Gastroenterol 1983;12;463-74, based on Borgstrom B, et al. Studies of intestinal digestion and absorption in the human. J Clin Invest 1957;1521-36.)*

occurs, leading to diarrhea, flatulence, and weight loss. Paradoxically, diabetes mellitus causes a striking increase in sucrase-isomaltase activity; an increase is also observed in monosaccharide and amino acid transport. The lactase–phlorizin hydrolase complex is the only brush border enzyme able to hydrolyze lactose and is therefore essential to survival of mammals early in life.

This complex also has glycosylceramidase, β-glycosidase, and phlorizin hydrolase activities. Infectious and inflammatory diseases greatly reduce lactase–phlorizin hydrolase activity, leading to symptomatic intolerance to milk. Recovery of the enzyme activity following intestinal disease may be slow. The activity of the complex is resistant to starvation. The developmental regulation of lactase is discussed later in the section on disaccharidase deficiencies. Also present in the brush border is the α-glucosidase maltase-glucoamylase, which removes individual glucose molecules from the nonreducing end of α(1,4) oligosaccharides and disaccharides. This enzyme accounts for about 20% of the total maltase activity of the small intestine. Trehalase is also found in the brush border of the small intestine and hydrolyzes trehalose, an α(1,1) disaccharide of glucose found in yeast and mushrooms. The developmental pattern of trehalase appears to follow that of sucrase-isomaltase.

In addition to their actions on disaccharides, the brush border enzymes further hydrolyze the products of amylase action, including maltose, maltotriose, and α-limit dextrins. The brush border enzymes appear to act in an integrated manner in that there is a flow of substrate from glucoamylase and isomaltase to sucrase with the production of the monosaccharides glucose, galactose, and fructose. These monosaccharides are transported into the enterocyte by facilitative transport systems, such as the Na^+-dependent glucose (and galactose) transporter (SLGT1) and GLUT5 (one of the GLUT family of genes for monosaccharide transport), which transports fructose across the apical membrane of the enterocyte. Subsequently, absorbed glucose and fructose are transported across the basolateral membrane and out of the enterocyte and into the portal system by the GLUT2 transporter.

It is increasingly being realized that the limiting factor in carbohydrate digestion and absorption may be diffusion from the intestinal lumen to the membrane surface where the enzymes are localized. There is normally little disaccharidase activity in the luminal contents. For most oligosaccharides (with the exception of lactose), hydrolysis is rapid, and transport is the rate-limiting step in reducing the concentration of monosaccharides and the osmotic load in the gut. When the transport system is operating at its maximum rate but monosaccharide concentration is still high, inhibition of hydrolases by their monosaccharide products (i.e., product inhibition) slows hydrolytic activity, keeping monosaccharide concentrations relatively constant, thereby controlling osmotic load and water concentration in the gut. The importance of this control is evident from the consequences of intestinal disorders in which ingested disaccharide is not split and absorbed. The presence of undigested disaccharide increases fluid secretion into the gut and increases intestinal motility. Enteric bacteria ferment the unabsorbed sugars, producing hydrogen, carbon dioxide, and organic acids. Abdominal discomfort such as bloating, distention, and cramping occurs; absorption of fermentation products may lead to metabolic acidosis. In the large bowel, the presence of CO_2 and organic acids decreases pH

TABLE 48-1 Brush Border Oligosaccharidases

Enzyme or Complex	Principal Substrate(s)	Products
β-glycosidase complex:		
Lactase (EC 3.2.1.23)	Lactose	Glucose + galactose
Glycosylceramidase (EC 3.2.1.45-46) (also called phlorizin hydrolase [EC 3.2.1.62])	Galactosyl and glucosyl-β-ceramides	Galactose/glucose + ceramides
Sucrase-isomaltase complex:		
Sucrase-(maltase) (EC 3.2.1.48)	Maltose/sucrose	Glucose/fructose + glucose
Isomaltase-(maltase) (EC 3.2.1.10)	1,6-α-linkages in isomaltose and α-dextrins	Glucose
	Maltose	Glucose
Trehalase (EC 3.2.1.28)	Trehalose	Glucose
Glucoamylase complex (EC 3.2.1.20):		
Glucoamylase-(maltase)-1 and glucoamylase-(maltase)-2 (have similar substrate specificities)	1,4-α-linkages at nonreducing ends of amylose, amylopectin, glycogen, and straight chain 1,4-α-glucopyranosyl oligomers, including maltose	Glucose

From Semenza G, Auricchio S. Small intestinal disaccharidases. In: Scriver CR, Beaudet AL, Sly WS, Valle D, eds. The metabolic and molecular bases of inherited disease, 7th ed. New York: McGraw-Hill, 1995:4451-80.

and keeps the osmolality high so that water reabsorption is decreased. The result is an acidic, liquid stool. Normally, however, accumulation of monosaccharide products does not occur, because the transport system is sufficiently fast to remove them. Mucosal lactase activity is the lowest of all the disaccharidases; for lactose, the rate-limiting step in absorption is thought to be hydrolysis. Lactase activity is not increased by feeding large amounts of lactose, as is the case for maltase and sucrase. Lactase, maltase, and sucrase all show circadian rhythms in their activities; minimum and maximum activities may vary by a factor of 2.

Carbohydrate digestion is not always complete in the small intestine. Indeed, it is likely that some starch and sucrose normally pass undigested and unabsorbed into the colon. It has been estimated that colonic bacteria require 70 g of carbohydrate/day. Much of this is derived from endogenous sources, such as from glycoproteins in GI secretions, with the remainder coming from unabsorbed dietary carbohydrate and dietary fiber. Up to 15% of the carbohydrate from white bread reaches the colon, and the effects of indigestible oligosaccharides on reaching the large bowel are well known. As pointed out earlier, bacterial action creates short-chain fatty acids, which are rapidly absorbed by the colonic mucosa and are thought to provide fuel for the colonocyte. Starch and oligosaccharides are osmotically active and draw water into the gut. The colon, however, can absorb up to four times the normal colonic water load; for this reason, diarrhea is not always present in oligosaccharide malabsorption.

Digestion and Absorption of Lipids

The recommended daily dietary fat intake in Europe and North America is 70 to 95 g. Less than 5 g/24 hours is recovered in the feces, indicating the overall efficiency of the normal processes of fat digestion and absorption. Most dietary fat is in the form of long-chain triacylglycerols (triglycerides). Pancreatic lipase is quantitatively the most important hydrolytic enzyme, but the contribution of gastric lipase to overall hydrolysis should not be underestimated. Gastric lipase is secreted by the gastric mucosa and normally accounts for up to 17.5% of fatty acids released from triglycerides following a meal.[20] The enzyme has a wide pH optimum and is active in both the stomach and duodenum. This nonpancreatic lipase may have a significant role in lipid digestion when pancreatic function is impaired and in the neonatal period before pancreatic lipase activity is fully developed. A lingual lipase is also present, secreted by the tongue, but is thought not to be of much significance normally in humans.

Fats are first emulsified in the stomach by its churning action and stabilized by interaction with luminal lecithin and protein fragments. The lingual and gastric lipases do not require bile salts or cofactors to function; they have a pH optimum of 3 to 6 and their action produces 1,2-diacylglycerols and fatty acids. These products further stabilize the surface of the triglyceride emulsion and in the duodenum promote the binding of pancreatic colipase. In addition, the liberated fatty acids stimulate release of CCK from the duodenal mucosa.

Pancreatic lipase, in the presence of bile salts and colipase, acts at the oil-water interface of the triglyceride emulsion to produce fatty acids and 2-monoacylglycerols. Colipase is secreted in pancreatic juice as an inactive proenzyme, which is converted to the active form by trypsin. Other significant enzymes involved in the breakdown of fats within the intestinal lumen are cholesterol ester hydrolase, phospholipase A_2, and a nonspecific bile salt–activated lipase.

Only a small proportion of ingested triacylglycerol is completely hydrolyzed to glycerol and fatty acids. These products form micelles with bile salts and lysophosphoglycerides; the micelles convey the nonpolar lipid molecules from the lumen to the epithelial cell surface and dissociate there to produce a high concentration of monoacylglycerols, lysophosphoglycerides, and fatty acids, which are absorbed into the mucosal cell. This absorption is facilitated by a fatty acid–binding protein in the cytosol of the cell that has a high affinity for fatty acids. Within the cell, triacylglycerols are resynthesized from the absorbed 2-monoacylglycerols and fatty acids. The triacylglycerols, together with phospholipids, cholesterol and its esters, fat-soluble vitamins, and a specific apolipoprotein, are formed into chylomicrons, which are then released by exocytosis into the lymphatic system of the small bowel.

From the lymphatics, chylomicrons enter the blood stream via the thoracic duct and are distributed to the liver, adipose tissue, and other organs. Medium- and short-chain fatty acids (chain length <12 carbon atoms) in mixed triglycerides are preferentially split by lipases and pass into the aqueous phase from which they are rapidly absorbed. Medium-chain triglycerides can be absorbed without complete lipolysis and in the absence of bile. They do not require micellar solubilization and are transported from the intestinal epithelial cells predominantly via the hepatic portal vein. Figure 48-4 summarizes the processes involved in fat absorption and conditions that compromise the efficiency of one or more stages in the process of fat digestion and absorption leading to fat malabsorption.[26]

Digestion and Absorption of Proteins

The average daily dietary intake of protein in North America is about 100 g compared with an estimated requirement for adults of 50 to 70 g. In addition to dietary protein, another 50 to 60 g of protein enters the intestinal contents daily in GI secretions and from desquamated mucosal cells. Normal daily fecal loss of protein is about 10 g.

Protein digestion is initiated in the stomach by the action of pepsin in a highly acid medium. The acidity also denatures the protein, unfolding the polypeptide chains for better access by the gastric, pancreatic, and intestinal proteolytic enzymes. Additionally, the polypeptides and amino acids

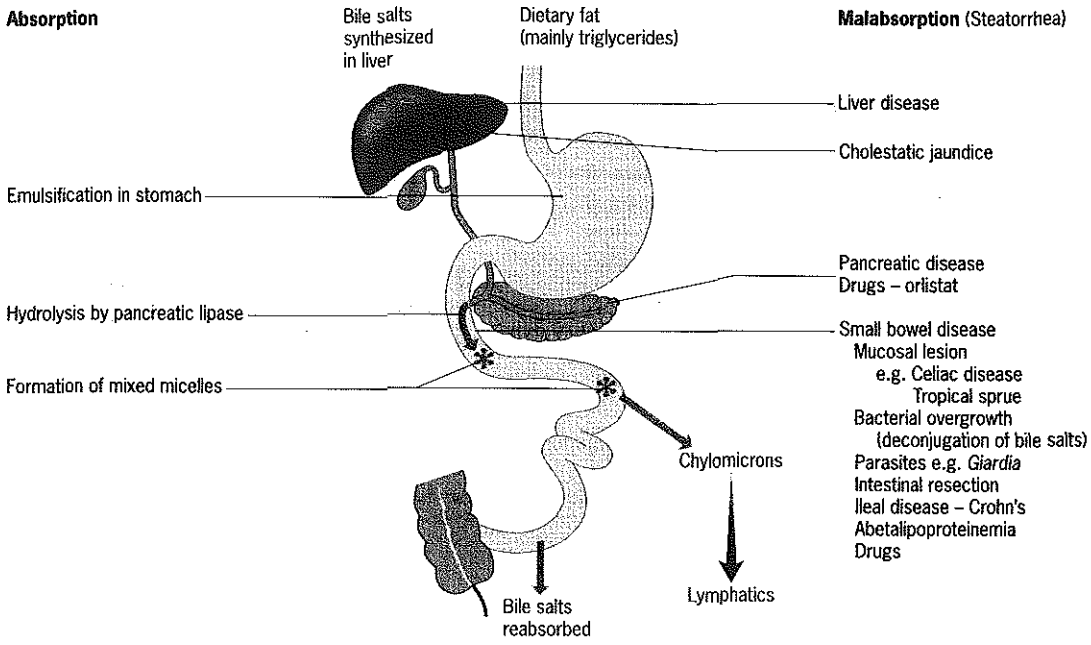

Figure 48-4 Summary of the processes involved in fat absorption and malabsorption. *(From Clark ML, Silk DB. Gastrointestinal disease. In: Kumar P, Clark M, eds. Clinical medicine, 5th ed. Edinburgh: WB Saunders, 2002:253-333.)*

produced in the stomach by the action of pepsin are potent secretagogues for the hormones that stimulate the pancreas and intestine. Stimulated pancreatic secretion contains the proenzyme forms of the proteolytic enzymes trypsin, chymotrypsin, elastase, exopeptidases, and carboxypeptidases. Proteolytic enzymes are either endopeptidases (e.g., pepsin, trypsin, chymotrypsin, and elastase), which hydrolyze peptide bonds within the polypeptide chain, or exopeptidases, which hydrolyze peptide bonds of the terminal amino acids (enzymes such as carboxypeptidase and aminopeptidase). Stimulation of the intestine by GI hormones liberates several proteolytic enzymes from the brush border. One of them, enterokinase, selectively cleaves a hexapeptide from the *N*-terminus of trypsinogen to form trypsin. Trypsin then activates more trypsin (autocatalysis) and in addition converts other pancreatic proenzymes into their active forms. The action of the pancreatic enzymes on the partly digested proteins within the lumen produces peptides, 2 to 6 amino acid residues in length, and also single amino acids. The peptides are largely hydrolyzed to single amino acids by the aminopeptidases and dipeptidases of the brush border before absorption, although some dipeptides and tripeptides are absorbed and are hydrolyzed to amino acids by cytosolic peptidases within the enterocytes. At least seven carrier systems with overlapping specificities for different amino acids are involved in transport of amino acids into the cells. Absorption of amino acids by these transport systems is faster in the jejunum than in the ileum. The amino acids pass into the underlying rich vascular plexus, drained by the portal circulation, and it is by this route that absorbed amino acids reach the liver and then the systemic circulation.

Individuals with achlorhydria or total gastrectomy have normal protein digestion and absorption as small intestinal function compensates for the lack of pepsin activity. Pancreatic and small intestinal diseases are the major causes of protein maldigestion and malabsorption. However, fecal loss of protein rarely becomes significant in pancreatic insufficiency until trypsin levels fall to about 10% of normal. Two rare disorders, trypsin deficiency and enterokinase deficiency, have far-reaching effects on efficiency of protein digestion, as would be expected from their roles in the activation of proteolytic proenzymes. Mucosal diseases may affect protein assimilation by a number of mechanisms. Reduction in number of mucosal cells decreases peptidase activity in the intestine and intestinal absorptive capacity for amino acids. Disease may increase the turnover of intestinal cells and the rate of desquamation. This cell loss, together with increased losses of plasma proteins from the damaged intestinal surface, can cause a negative nitrogen balance. Surgical resection of the intestine not only reduces the total intestinal absorptive surface but also may remove a segment of the gut that is specialized for absorption of certain nutrients (for example, resection of the distal ileum removes the active transport system for the vitamin B_{12}–intrinsic factor complex). Resection may also alter intestinal motility and lead to stasis and bacterial overgrowth that can intensify a negative nitrogen balance. There are also rare hereditary defects in amino acid transporters that produce distinct syndromes.

STOMACH: DISEASES AND LABORATORY INVESTIGATIONS

The growth in endoscopic procedures, with direct visualization of the interior of the stomach, has largely removed the need for the clinical laboratory to carry out the analysis of gastric contents. Situations remain, however, in which the laboratory continues to play a significant role in the diagnosis of gastric diseases and in monitoring the effectiveness of treatment. This section describes peptic ulcer disease and tests for *Helicobacter pylori* (*H. pylori*) and the measurement of basal acid output from the stomach.

Peptic Ulcer Disease and *Helicobacter pylori*[155,165]

Although the presence of spiral-shaped organisms in the stomach has been acknowledged for many years, it was only in 1985 that the association was described between *H. pylori* (known then as *Campylobacter pylori*) and peptic ulcer disease.[125] Most estimates suggest that the bacterium is present in the mucous layer of the stomach in half of the population of the world. In Europe 30% to 50% of adults, and in the United States at least 20% of the adult population, are infected with the organism. In all cases, colonization with *H. pylori* causes a chronic inflammatory reaction in the gastric mucosa even when direct endoscopic observation of the mucosa appears normal. Carriers of the organism are at increased risk of gastric cancer (twofold to tenfold) and peptic ulcer (threefold to tenfold).[12] Some of the increased risk is due to infection with strains of the organism that produce the cytotoxic cagA protein. About 90% of gastric cancer patients are infected with *H. pylori*, compared with 40% to 60% of age-matched controls.[139,140] In a European study comparing prevalence of *H. pylori* and gastric cancer rates in 13 countries, a significant correlation was observed between the infection rate and gastric cancer incidence and mortality.[169] It is, however, important to remember that although a large proportion of gastric cancer can be attributed to infection with *H. pylori*, only in a minority of infected subjects will the inflammatory reaction progress to gastric cancer. The current consensus is that asymptomatic subjects should not be screened for *H. pylori* infection.[123]

At least 95% of patients with duodenal ulcer disease are infected with *H. pylori*, and eradication of the organism leads to healing of the ulcer and reduction in relapse rates.[145] Eradication of *H. pylori* is now the recommended treatment for patients with duodenal or gastric ulcer who are *H. pylori*–positive. Effective combined antibiotic and acid suppression regimens (using PPIs) are available with eradication rates of about 90% after first-line treatment.[165]

H. pylori infection predominantly affects the gastric mucosa, with the antrum usually being the most densely colonized area. The reasons that a gastric mucosal infection predisposes to duodenal ulceration are complex and involve a number of pathways leading to increased acid production. Before there was an awareness of the role of *H. pylori* in the pathogenesis of peptic ulcer disease, vagotomy (surgical sectioning, or cutting, of the vagus nerve) was the mainstay of treatment as a means of reducing gastric acid output, thereby leading to an environment more conducive to healing of the ulcer.

Infection with the organism, with or without duodenal ulceration, leads to increases in both basal and meal-stimulated serum gastrin concentrations, principally due to an increase in gastrin-17.[134] Basal acid output is increased in *H. pylori*–positive subjects (see Figure 48-5), and resolves completely after successful eradication of the organism. Hypergastrinemia is believed to be only one of the mechanisms leading to increased acid output. Studies using the neuropeptide gastrin releasing peptide (GRP) suggest that impairment of inhibitory control mechanisms regulating acid production may be responsible for the increased acid output associated with *H. pylori* infection.[49] In addition to stimulating the G cells of the antrum to release gastrin, which leads to acid secretion by parietal cells, GRP also activates neuroendocrine pathways that inhibit gastric acid secretion, an effect mediated via several peptides (including cholecystokinin and secretin) that stimulate the release of the inhibitory peptide somatostatin from the gastric mucosa.

H. pylori produces urease, and hydrolysis of endogenous urea to bicarbonate and ammonia may create a more hospitable microenvironment for the survival of the organism in the stomach. Mammalian cells do not hydrolyze urea and it was only in 1984 that "gastric urease" was associated with the presence of *H. pylori*.[110] The ability of the organism to rapidly hydrolyze urea is the basis of the urea breath tests and of the direct urease tests on gastric biopsy samples.

Diagnostic Tests for *H. pylori*

A wide range of invasive and noninvasive diagnostic tests for *H. pylori* has been described as shown in Box 48-1.

All of the tests in the "invasive" group necessitate oral gastroduodenoscopy with a biopsy of the gastric mucosa; false negative results may occur because of sampling errors, as colonization may be patchy. The antrum is the preferred biopsy site, but multiple biopsies from the anterior and posterior walls of the antrum and body of the stomach are recommended for maximum diagnostic accuracy of this group of tests. False negatives may also occur when biopsies are taken during treatment with PPIs or within 2 weeks of stopping PPI therapy. This group of drugs alters the intragastric distribution of *H. pylori* and suppresses its activity.[118] PPIs can also lead to falsely negative urea breath test results. During PPI therapy, biopsies should also be taken from the body and fundus to prevent false negatives. If PPIs cannot be withheld for at least 2 weeks before a breath test, a negative result must be interpreted with caution. Histamine H_2-receptor antagonists and antacids do not affect the tests in this way.

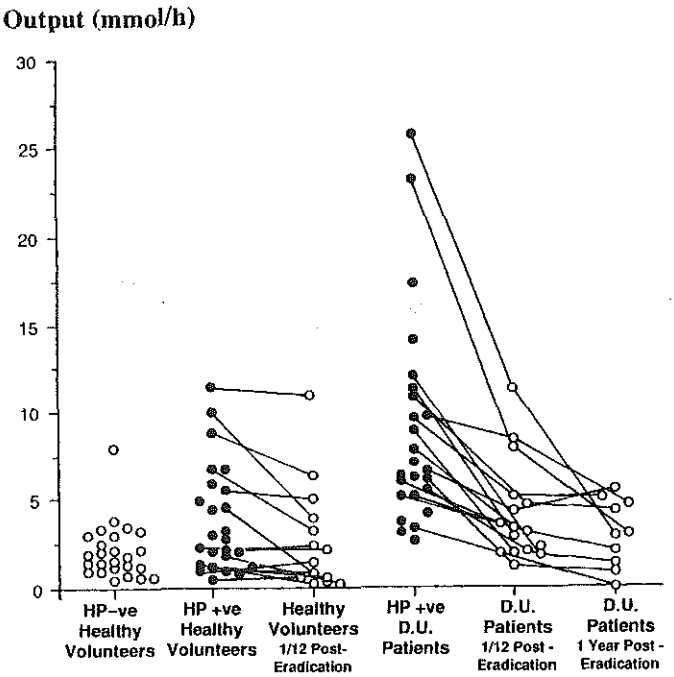

Figure 48-5 Basal acid output in healthy volunteers and patients with duodenal ulcers (DUs) of varying *H. pylori* status (●, *H. pylori* positive). Compared with *H. pylori*–negative healthy volunteers, basal acid output is increased in *H. pylori*–positive healthy volunteers ($P < 0.05$), *H. pylori*–positive patients with DUs ($P < 0.0001$), and patients with DUs 1 month after eradication ($P < 0.01$). *(From El-Omar EM, Penman ID, Ardill JES, Chittajallu RS, Howie C, McColl KEL. H. pylori infection and abnormalities of acid secretion in patients with duodenal ulcer disease. Gastroenterology 1995;109:681-91, with permission from the American Gastroenterological Association.)*

BOX 48-1 Diagnostic Tests for *Helicobacter pylori*

Invasive Tests—Using Gastric Mucosal Biopsy Samples

- Histology: microscopy after Giemsa or silver staining
- Histology: microscopy after immunohistochemical staining
- Direct urease test: a biopsy incubated in urea/indicator solution; visual endpoint
- Culture: incubation on suitable media for 4 to 10 days
- Polymerase chain reaction: amplification of specific DNA sequences

Noninvasive Tests—Using Breath, Blood, Saliva, or Feces

- Breath tests: rise in breath $^{14}CO_2$ or $^{13}CO_2$ after ingestion of ^{14}C- or ^{13}C-labeled urea
- Serum tests: laboratory measurement of specific IgG antibody
- Whole blood tests: point-of-care tests for specific IgG antibody
- Saliva tests: detection of specific IgG antibody
- Fecal tests: detection of specific antigen

Tests for *H. pylori* are required for diagnosis of the infection and to ascertain, in some situations, that eradication therapy has been successful. High sensitivity is required to ensure that positives are not missed; similarly, high specificity is essential to prevent inappropriate use of eradication therapy. The Maastricht 2-2000 Consensus guidelines[123] recommend a "test and treat" strategy in adults with appropriate dyspeptic symptoms under the age of 45 years using either the breath test or stool antigen test. The age limit may vary depending on local prevalence and the age distribution of gastric cancer (e.g., in the United Kingdom, testing and treatment are now recommended up to the age of 55 in patients with uncomplicated dyspepsia).[15] Successful eradication should be confirmed with the urea breath test or by a direct urease test if endoscopy is clinically indicated; the stool antigen test may be used if urea breath tests are not available. Other national guidelines confirm the urea breath test as the preferred procedure, both for initial diagnosis and for confirmation of eradication.[15,87] Testing to confirm eradication should be done at least 4 weeks after completion of the course of treatment.

Urea breath tests are simple to perform, and sensitivity and specificity are both greater than 95%. Urea labeled with either ^{14}C or ^{13}C is given orally as a drink or a capsule to swallow with water; urease from gastric *H. pylori* rapidly hydrolyzes the ingested urea to produce labeled bicarbonate, which is absorbed into the blood and exhaled as $^{14}CO_2$ or $^{13}CO_2$. The principal advantages of the ^{13}C-urea breath test over the ^{14}C-urea breath test are the simplicity of breath collection and the avoidance of the regulations and environmental issues related to the use and disposal of radioisotopes. In the ^{14}C-urea breath test, CO_2 in expired air is trapped in methanolic hyamine hydroxide as the patient exhales through a straw, which should be fitted with a one-way valve to ensure the patient does not suck the trapping solution into the mouth. A color change of an indicator (thymol blue) in the solution shows that the required quantity of CO_2 has been trapped. Scintillant is then added and $^{14}CO_2$ measured. In the ^{13}C-urea breath test, the patient blows through a straw into an empty 15 mL tube, which is then capped. $^{13}CO_2/^{12}CO_2$ ratios are compared for basal and postdose samples using isotope ratio mass spectrometry or alternative infrared measurement methods.[106,117]

In the stool test, specific *H. pylori* antigens are detected in microtiter plates coated with polyclonal antibodies. Debate continues regarding its accuracy for assessing treatment outcome; some of the variability in results between different studies appears to be caused by lack of standardization of the interval between completion of eradication therapy and stool testing.[174] However, the test is currently recommended for posteradication testing if the urea breath test is not available.[123]

Although still widely available, serological tests are no longer recommended. The systemic antibody response is variable, leading to equivocal results in some subjects; in subjects age >50 years, diagnostic accuracy is unsatisfactory. Serology cannot be used to confirm eradication because of the slow decline in antibody levels after treatment. Laboratory-based enzyme-linked immunosorbent assays (ELISA) assays and point-of-care tests are available to measure specific IgG antibodies in serum or whole blood samples. In younger subjects, the laboratory-based tests generally perform well although some have sensitivity and/or specificity of <95%. Office-based serology currently has inadequate sensitivity and specificity. Calculations based on reported diagnostic accuracy data show that when these tests are used for diagnosis, as many as 28% of those receiving eradication therapy are being treated as a result of false-positive test results.[25]

Since 1985, an enormous body of literature has accumulated on the epidemiology and transmission of *H. pylori*, on pathogenicity and host response, and on clinical outcomes and treatment options. Despite the clear link with peptic ulcer disease, the question of whether *H. pylori* causes duodenal ulceration or is just an important factor producing recurrence and chronicity continues to be raised.[13] Another interesting area is the use of gene expression studies to increase understanding of the interaction between the gastric mucosa and *H. pylori* by comparison of gene products from gastric tissue *H. pylori* and isolated strains grown in vitro.[67] It is an organism that will continue to surprise us.

Determination of Basal Acid Output[36,76,93]

The documentation of an increased basal acid output (BAO) in gastric juice provides strong evidence that a high serum gastrin concentration is caused by Zollinger-Ellison syndrome. The test is therefore used in patients with duodenal ulceration and a raised serum gastrin concentration. The test is not appropriate in patients with atrophic gastritis. Pernicious anemia, which also causes hypergastrinemia, should be excluded before assessing BAO. PPIs must be stopped for at least 14 days, and H_2-receptor antagonists for at least 3 days, before the test. *H. pylori* as a cause of increased serum gastrin should also be excluded before BAO estimation.

A basal condition, in the context of gastric analysis, is one in which the patient is at complete rest and not exposed to any visual, auditory, or olfactory stimuli. Such a condition is maintained during sleep. It is for this reason that traditionally a 12-hour overnight collection of gastric juice has been used for the determination of BAO. Such an approach has the disadvantage that the patient is exposed to significant discomfort because of the need to retain the tube overnight, while sitting upright and slightly turned to the left to prevent a loss of gastric contents into the duodenum. Close supervision throughout the entire night is necessary. A satisfactory alternative is the collection of gastric juice for 60 minutes after the patient has had a satisfactory night's sleep in a quiet separate room. After waking, the patient must remain fasting; smoking and exercise must be avoided before and during the test.

Collection of Gastric Juice

A gastric tube is inserted orally, or nasal intubation may be used if the patient has a hyperactive gag reflex. X-ray or fluoroscopic confirmation that the tip of the radio-opaque tube is in the lowest portion of the stomach is necessary. Ten or 15 minutes after the patient has become calm and adjusted to the presence of the tube, the patient is positioned with the trunk upright and inclined slightly to the left. Gastric juice is then aspirated and discarded. After checking that no further juice can be aspirated, note the time and collect and transfer to plastic bottles all gastric juice that can be aspirated over the next 60 minutes. The patient must be asked to expectorate all saliva during the collection period. The total volume of the collected juice is recorded and free acid determined by titration as described below.

Determination of Free Hydrochloric Acid in Gastric Juice

1. Measure and transfer a convenient volume of gastric juice (e.g., 5.0 to 10.0 mL) into a clean titration vessel. If the gastric juice contains food particles or mucus, centrifuge the sample or filter it through gauze.
2. Determine the pH of the gastric specimen with a pH meter. If the pH is above 3.5, no free acid is present. Such a specimen need not be titrated.
3. Titrate the sample with NaOH, 0.10 mol/L, to a pH of 3.5, using a pH meter.

Calculation:

$$\text{Free HCl (mmol/L)} = \frac{\text{mL of NaOH} \times 100}{\text{mL of gastric juice titrated}}$$

If 5 mL of gastric specimen is titrated, the calculation becomes:

$$\text{Free HCl (mmol/L)} = \text{mL of NaOH} \times 20$$

$$\text{Free HCl (mmol/hr)} = \frac{\text{mL of NaOH} \times 20 \times 60\text{min volume of gastric juice in mL}}{1000}$$

Comments and Sources of Error

Titration to a pH of 3 to 3.5 detects essentially all free hydrochloric acid. (Because HCl is the only strongly ionized

acid in gastric content, this test is essentially a test for free HCl.) Titration beyond a pH of 3.5, as recommended by some, will overestimate the HCl concentration to varying degrees, depending on the composition of the gastric residue. On the other hand, titration to pH 3.5 may underestimate the amount of free H^+ secreted if some of these H^+ ions are bound to or have reacted with other constituents of gastric content. Thus no fully satisfactory procedure is available to measure accurately the true total amount of free acid secreted by the gastric mucosa.

The effectiveness of gastric aspiration may be compromised both by the position of the patient and the position of the tube in the stomach (likened to the position of a straw above or below the fluid level in a glass), by the loss of gastric fluid into the pylorus, and by regurgitation of pyloric contents into the stomach. Some evidence suggests that the exact position of the tube in the stomach does not appear to alter the recovery of gastric juice, because the stomach is not rigid and its walls contract, thus shifting the stomach contents toward the tip of the tube.

Interpretation

Gastric juice pH: if the pH is >2.5, then it is unlikely that the raised gastrin is caused by Zollinger-Ellison syndrome.

BAO: Normal: male 0 to 10.5 mmol/hr; female: 0 to 5.6 mmol/hr

Zollinger-Ellison syndrome: 15 to 100 mmol/hr, or >5 mmol/hr if there was previous acid-reducing surgery.

A level of free acid >15 mmol/hr should prompt a suspicion of gastrinoma but is not diagnostic; a level >25 mmol/hr with high serum gastrin is virtually diagnostic of Zollinger-Ellison syndrome.

Further discussion of the Zollinger-Ellison syndrome can be found in the section of this chapter on neuroendocrine tumors.

INTESTINAL DISORDERS AND THEIR LABORATORY INVESTIGATION

This section includes a discussion of celiac disease, disaccharidase deficiency, bacterial overgrowth, bile salt malabsorption, and protein-losing enteropathy and the main laboratory investigations associated with their diagnosis.

Celiac Disease (Celiac Sprue, Gluten-Sensitive Enteropathy)[53,54,124,157]

Celiac disease is sometimes called nontropical sprue, celiac sprue, or gluten-sensitive enteropathy.

Pathophysiology of Celiac Disease

Celiac disease occurs in genetically predisposed subjects as a consequence of an inappropriate T-cell–mediated immune response to the ingestion of gluten from wheat and to similar proteins in barley and rye.

The role of genetic factors in celiac disease has been recognized for many years; there is a 70% concordance for celiac disease in identical twins and typically 10% of first-degree relatives of an affected individual will also be found to have the disease. Only recently has the major genetic component been localized to the human leukocyte antigen (HLA) region of chromosome 6. Approximately 95% of subjects with celiac disease express a specific HLA heterodimer (HLA DQ2 α/β heterodimer). Most Caucasian populations have a high frequency (20% to 30%) of DQ2, but only a small minority will develop celiac disease.

The external trigger to the development of celiac disease in genetically susceptible individuals is found in gluten, which is the complex group of proteins present in wheat that form a sticky mass when dough is washed with water and the starch is removed. All of the proteins (and peptides) that are toxic to the small bowel mucosa in subjects with celiac disease contain large amounts of glutamine. The major toxic proteins of wheat are the gliadins, with homologous proteins (the hordeins and secalins) occurring in barley and rye, respectively. The gliadins are a large family of proteins accounting for about 50% of the wheat protein.

Recent evidence indicates that oats do not lead to an immune-mediated response nor to mucosal damage in subjects with celiac disease.[92] Addition of oats to the list of permitted cereals increases choice and would be welcomed by most subjects with celiac disease. However, if oats are to be introduced into the diet they must be from a reliable source to ensure no contamination from wheat, barley, or rye proteins at any stage in the process from harvesting to packaging.

The identification in 1997 of small bowel tissue transglutaminase (tTG)-2 as the auto-antigen of celiac disease[37] was a major step forward in understanding the pathogenesis of the disorder. The tissue transglutaminases are a family of calcium-dependent cytoplasmic enzymes that are released from cells during wounding. Although their physiological role is incompletely understood, they are able to catalyze the cross-linking of proteins leading to the stabilization of the wound area. Expression of the enzyme is increased during apoptosis and in active celiac disease. It selectively cross-links or deamidates protein-bound glutamine residues. Deamidation of gliadin peptides by the enzyme enhances their binding to HLA DQ2/DQ8 and increases the recognition of these peptides by gut-derived T cells from subjects with celiac disease.[158] The pathogenesis of the disease is therefore believed to involve an interaction between tissue transglutaminase and gliadin peptides in genetically susceptible individuals.

The toxic cereal proteins lead to intestinal epithelial damage, releasing tissue transglutaminase. Cross linking by the enzyme produces gliadin-gliadin or gliadin-enzyme complexes, unmasking new antigenic epitopes that bind to HLA DQ2 molecules on the antigen-presenting cells, producing an immune response by gut-derived T cells. The characteristic enteropathy is then induced by the release of interferon-γ and other proinflammatory cytokines as outlined in Figure 48-6.

A 33-mer peptide of gluten appears to be the primary initiator of the inflammatory response.[154] It is resistant to breakdown by all gastric, pancreatic, and intestinal brush-border membrane proteases, thus allowing it to reach the small intestine intact. After deamidation by tissue transglutaminase, it is a potent inducer of gut-derived human T-cell lines from patients with celiac disease. Homologs of the peptide are found in food grains that are toxic to patients with celiac disease, but are absent from nontoxic food grains. The peptide could be detoxified by exposure to a bacterial prolyl endopeptidase, suggesting a strategy for therapy of celiac disease.[154]

Increased intestinal permeability in untreated celiac disease that is reversible on withdrawal of gluten from the diet has been recognized since the early 1980s.[74] Recent evidence suggests that this may be mediated by increased expression of zonulin,[56] a protein that opens small intestinal tight junctions, or to decreased expression of intercellular epithelial cell adhesion molecules, such as ZO-1, catenin, and cadherin.[142] It is currently unclear whether these findings are

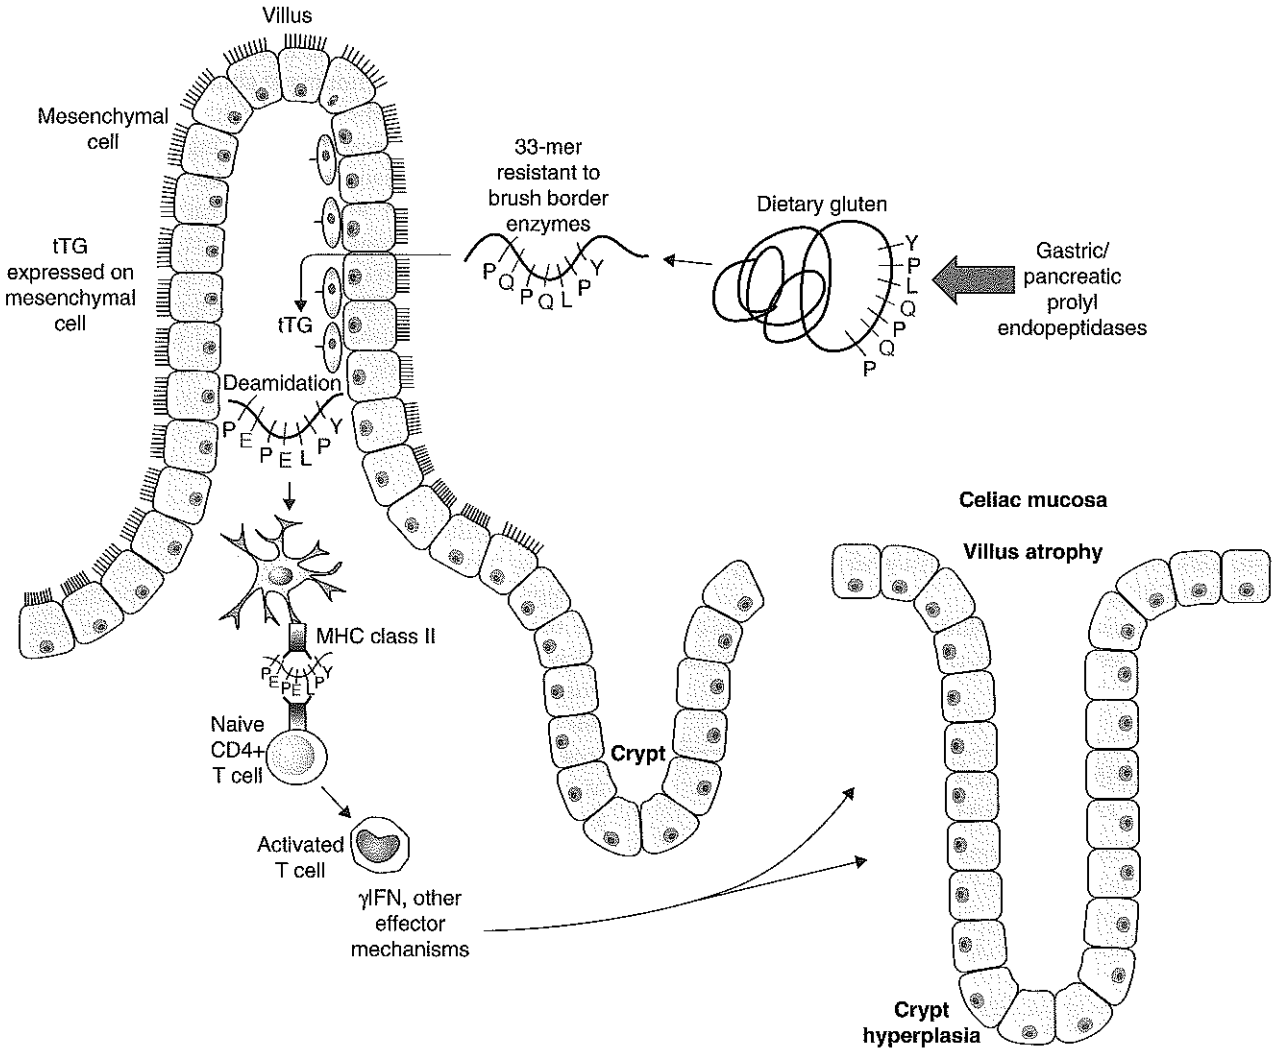

Figure 48-6 Hypothetical scheme for interaction between intestinal protein processing and the specific immune system in celiac disease. Dietary gluten is exposed to intraluminal digestive enzymes (including prolyl endopeptidases), producing stable 33-mer peptide-containing overlapping proline-rich epitopes with PQPQLPY central motif. 33-mer peptide is absorbed intact by transcellular or paracellular routes into lamina propria, and exposure to tTG results in deamidation of glutamine residues to glutamic acid. Modified peptide is presented to specific CD4+ T cells in association with HLA DQ2 or DQ8. Activated IFN-γ producing T-effector cells return to mucosa and produce characteristic villus atrophy and crypt hyperplasia. *tTG*, Tissue transglutaminase, *IFN*, interferon. *E*, glutamate, *F*, phenylalanine, *L*, leucine, *P*, proline, *Q*, glutamine, *Y*, tyrosine. *(From Mowat AM. Coeliac disease—a meeting point for genetics, immunology, and protein chemistry. Lancet 2003;361:1290-2.)*

linked to the entry of allergens into the cell and hence to the autoimmune response.

Clinical Considerations

Celiac disease is a common chronic disorder in Caucasian populations with a prevalence of about 1%.[122,181] It also occurs in northern Indian and in North African populations. It is rare in Chinese, Japanese, and African-Caribbean people. It was previously considered to be a rare disorder in North America, but recent serological and histological evidence shows that the disease has been underdiagnosed and that the prevalence is comparable, as might be expected, with that found in Europe.[55,78]

There is a wide spectrum in the clinical presentation of celiac disease, with the majority of diagnoses made in adult life. Classical celiac disease, presenting in infancy, up to the age of 2 years, with failure to thrive, abdominal distension, and diarrhea is now an uncommon presentation. The spectrum of presenting symptoms in adults has changed over the last 20 years, and frank malabsorption is now uncommon.[88,180] Most adults present now with nonspecific symptoms; mild iron deficiency is common. There is a strong association with other autoimmune disease, especially with type 1 diabetes mellitus and autoimmune thyroid disease. In type 1 diabetes, the prevalence of celiac disease is about 5% and serological screening to detect these cases has been advocated.[85] The initial presentation may be to a wide range of clinical specialties as shown in Table 48-2. To make the diagnosis there must be a high index of suspicion with an awareness of the wide range of nonspecific symptoms and easy availability of serological tests to select those patients in whom endoscopy is indicated to confirm the diagnosis.

Tests for Celiac Disease

Serological tests have played a significant role in the growing awareness of the high prevalence of the disorder, and appropriately standardized tests have high sensitivity and specificity for diagnosis and for monitoring treatment compliance with a gluten-free diet.

Table 48-3 compares the sensitivity and specificity of the four IgA-class antibodies commonly used. The antireticulin (ARA) and endomysial (EMA) antibodies are both measured by indirect immunofluorescence, ARA on rat kidney sections and EMA on monkey esophagus or human umbilical cord sections. Rat kidney sections are frequently used as one of the substrates for autoantibody profiles, and the presence of ARA indicates the need to measure antibodies with higher specificity before recommending small bowel histology for confirmation of the diagnosis. Recent evidence has confirmed that ARA and EMA are tissue type–dependent methods, which detect autoantibodies to tissue transglutaminase-2.[107]

Lack of standardization of assays for IgA-antigliadin antibodies (AGA) contributes to the variable diagnostic accuracy of this marker,[81] but sensitivity of AGA is inferior to that of EMA. In some reports, comparison of sensitivity is compromised by selection bias,[115] but most larger series in which patients have not been selected for a biopsy solely on the basis of a positive EMA result indicate that the true sensitivity for EMA is between 90% and 95% (i.e., 5% to 10% of subjects with celiac disease have a negative EMA at diagnosis). When carried out correctly, the assay has very high specificity (>99%) and laboratories should monitor their performance, as small reductions in specificity will lead to significant increase in the numbers of patients subjected

TABLE 48-2 An Indication of the Wide Range of Clinical Specialties to Which a Child or Adult With Celiac Disease May Present

Clinical Specialty	Symptoms/Manifestations
General medicine	Tired all the time
Gastroenterology	Diarrhea, flatulence, weight loss
Hematology	Anemia
Obstetrics/gynecology	Infertility
Orthopedics	Fracture, osteopenia
Dermatology	Dermatitis herpetiformis, hyperkeratosis
Neurology	Peripheral neuropathy
Rheumatology	Arthropathy
Endocrinology	Short stature, thyroid disease
Diabetes	Diarrhea, anemia

TABLE 48-3 Comparison of Serological Tests for Celiac Disease

Antibody	Method	Sensitivity	Specificity
Antireticulin antibody (R1-ARA)	Immunofluorescence on rat or mouse kidney	25%-30%	>90%
IgA-endomysial antibody	Immunofluorescence on monkey esophagus or human umbilical cord	80%-100%	>99%
IgA-antigliadin antibody	Quantitative ELISA	75%-95%	95%
IgA-antitissue transglutaminase antibody (human antigen)	Quantitative ELISA	>90%	>99%

IgA, Immunoglobulin A; *ELISA*, enzyme-linked immunosorbent assay.

TABLE 48-4 Comparison of True and False Positives and Positive Predictive Values at Different Specificities Assuming a Prevalence of Celiac Disease of 3% in the Population (n = 1000) Tested (Test Sensitivity of 95%)

Specificity	True Positives	False Positives	Positive Predictive Value
90%	29	97	0.23
95%	29	49	0.38
98%	29	19	0.60
99%	29	10	0.74
99.5%	29	5	0.85

unnecessarily to a small bowel biopsy. Table 48-4 shows the effect of test specificity on the numbers of true and false positives per 1000 subjects tested and on the positive predictive value at a disease prevalence (in the population tested) of 3%, assuming a sensitivity of 95%.

Many commercial kits are now available to measure IgA antibodies against tissue transglutaminase ("transglutaminase antibody," TGA) using human recombinant tissue transglutaminase or purified human enzyme as antigen. Lack of standardization and differences in recombinant technology (e.g., the use of eukaryotic or prokaryotic organisms to produce tTG) can lead to varying performance.[11,126] Specificity should be evaluated using a large series of samples representative of those routinely tested, and procedures should be selected on the basis of high specificity (minimum 99%) and high sensitivity (>90%). The use of TGA has advantages over EMA. Unlike EMA, which may be subject to observer bias, TGA is a quantitative procedure and does not require the use of primate tissue. It can be automated and is therefore appropriate for larger numbers of samples. This test is replacing EMA as the antibody of choice for serological testing and for assessing dietary compliance of subjects on a gluten-free diet.[16,80]

For diagnosis, current guidelines require a jejunal biopsy with the characteristic villous atrophy, increased intraepithelial lymphocytes, and hyperplasia of the crypts.[124] Wider use of serology has led to the recognition of more cases with minimal histological changes and to the use of the terms "potential" and "latent" celiac disease.[84] Patients with positive EMA or TGA are described as having potential celiac disease when the jejunal biopsy has normal villi but shows subtle changes, such as increased numbers of intraepithelial lymphocytes. It is thought that in time these patients will develop a flat mucosa. The term "latent celiac disease" is used to describe patients who have at some time had positive antibodies and a flat mucosa that recovers on a gluten-free diet, but have also been found to have a normal mucosa while on a normal diet.

TABLE 48-5 Prevalence of Hypolactasia in Adults

Racial Group	Prevalence (%)
Chinese	>90
American blacks	54-81
Asians	60-90
Greeks	60-78
North Europeans	5-30

Subjects with selective IgA deficiency (IgA <0.05 g/L, incidence about 1:600) are at greater risk of celiac disease. It is therefore important to identify these individuals rather than risk excluding the diagnosis on the basis of a negative test for IgA-class antibodies.[24] When EMA is used, total serum IgA should be measured on all samples submitted for celiac serology to identify those patients with IgA deficiency. TGA assays should be designed so that the "normal" level is distinguishable from the small proportion of subjects with *very* low levels in whom total IgA measurement is indicated to confirm or exclude IgA deficiency. When IgA deficiency is identified, IgG antibodies (IgG-EMA, IgG-TGA) should be used as serological screening tests.[23] In view of the increased risk of the disorder in IgA deficiency, a small bowel biopsy should be considered in all IgA-deficient subjects with symptoms of celiac disease.[24]

Strict adherence to a gluten-free diet leads to mucosal recovery in celiac disease and reduces the risks of bowel malignancy. TGA can be used as a marker for monitoring dietary compliance in addition to its diagnostic role.[16]

With the availability now of serological tests with high diagnostic accuracy, older tests used to investigate celiac disease should be abandoned. There is, for example, no place now in routine use for the xylose absorption test. Dual sugar tests (e.g., cellobiose and mannitol) to assess small bowel permeability have a role in research studies but as yet have not established a place in the routine diagnosis or monitoring of celiac disease. Tests of fat malabsorption are also inappropriate in the diagnosis of celiac disease although appropriate tests of pancreatic function (e.g., fecal elastase) may be indicated in patients diagnosed with celiac disease who fail to respond to a gluten-free diet.

Disaccharidase Deficiencies

The presence of the brush-border disaccharidases is essential for carbohydrate absorption, and a reduction in their activity leads to carbohydrate malabsorption and intolerance. Carbohydrate malabsorption does not always lead to clinical symptoms, but when symptoms do occur (e.g., abdominal pain, flatulence, and diarrhea) as a consequence of the malabsorption, the patient is described as having carbohydrate intolerance.

Lactose intolerance is the single most common absorptive defect in adults, with an incidence of 5% to 90% depending on the racial group, as shown in Table 48-5.

Congenital Lactase Deficiency[59]

Intestinal lactase is essential in infancy, and congenital lactase deficiency is a very rare disorder in which lactase activities in the mucosa are low or undetectable at birth. Symptoms occur as soon as milk is taken; stools have a low pH and contain glucose produced by bacterial action on undigested lactose. Absent or low intestinal lactase in the neonate, however, cannot be taken as proof of congenital deficiency, because lactase is normally the slowest of the oligosaccharidases to reach normal levels in the newborn's gut. A definitive diagnosis must be deferred until after maturation of the lactase synthesis system has occurred. In the interim, relief is dependent on adjustments of dietary composition that appear to reduce severity of symptoms. An abnormal oral lactose tolerance test obtained a few months after birth could also be caused by congenital glucose-galactose intolerance (see discussion later in this chapter); the differential diagnosis requires performance of an oral glucose tolerance test in conjunction with the lactose tolerance test.

Acquired Lactase Deficiency

Expression of the enzyme diminishes with age and by adulthood lactase levels are 10% or less of those seen in infancy. If symptoms of flatulence, abdominal discomfort, bloating, or diarrhea occur after consumption of one or two glasses of milk or of a large portion of ice cream or yogurt, lactose intolerance should be suspected. Suspicion would be increased in a subject from an ethnic group with a high incidence of lactose intolerance (see Table 48-5).

Secondary lactose intolerance may occur as a result of reduced enzyme activity following diffuse intestinal damage from infections (giardiasis, bacterial overgrowth, or viral gastroenteritis), ulcerative colitis, celiac disease, and tropical sprue. This deficiency is usually reversible following recovery from the disorder.

Sucrase-Isomaltase and Trehalase Deficiencies and Monosaccharide Malabsorption

Sucrase-isomaltase deficiency usually presents clinically in infancy when sucrose and fruit are introduced in the diet,[101] but sometimes first presents in adulthood.[133,173] The deficiency is rare in Caucasians, but more common in Eskimo groups. Deficiencies of both lactase and sucrase-isomaltase may occur secondary to other small bowel diseases (e.g., celiac disease, Crohn's disease,[172] or acute gastroenteritis). Trehalase deficiency is a rare disorder,[135] except in Greenland, where it occurs in 8% of the population.[69] It is manifested by diarrhea following the ingestion of mushrooms.

Malabsorption of monosaccharides can also cause intestinal symptoms more commonly attributed to maldigestion of disaccharides. Glucose-galactose malabsorption is also inherited as an autosomal recessive trait. Symptoms occur in the affected neonate as soon as milk (lactose) is taken, but also follow ingestion of glucose- or galactose-containing foods. Symptoms caused by fructose malabsorption occur on ingestion of fruit. This dietary intolerance is quite a different disorder from hereditary fructose intolerance in which the hepatic enzyme aldolase is defective.

BOX 48-2 Methods for Detecting Lactase Deficiency

Lactase in mucosal biopsy
Oral lactose tolerance
- Measure increase in plasma glucose
- Measure increase in plasma galactose
- Measure increase in breath H_2
- Measure increase in breath $^{13}CO_2$

Diagnostic Tests for Lactase Deficiency

Many methods have been proposed for detecting lactase deficiency (Box 48-2). Disaccharidase activities can be measured in homogenates of an intestinal biopsy.[33] These assays are rarely required for routine diagnostic purposes, but when necessary (e.g., in investigations in infancy) they must be carried out by laboratories with expertise in these tests.

Oral Lactose Tolerance Tests

Oral tolerance tests, measuring the increase in plasma glucose or galactose following the ingestion of lactose, have also been used to diagnose lactase deficiency. The usual dose of lactose is 50 g in 200 mL water, although lower doses should be used in children (2 g/kg, up to a maximum of 50 g). Multiple blood samples are collected over a 2-hour period and the peak increment in glucose (or galactose) noted. To exclude lactase deficiency, the increase above baseline for capillary plasma glucose should be >1.1 mmol/L[137] (20 mg/dL) or >1.4 mmol/L (25 mg/dL) when using venous plasma.[22] In a recent survey of laboratory practice in the United Kingdom, widely varying cut-offs were found to be in use (1.0 to 2.7 mmol/L) even with the same lactose dose.[45] Procedures using galactose[90] are probably more popular with patients, as the test dose is preceded by a gin and tonic (equivalent to 300 mg ethanol/kg body weight). However, the requirement for multiple blood samples and lack of procedural standardization suggest that these tests should be abandoned in favor of noninvasive breath-hydrogen testing.

Hydrogen is not an end-product of mammalian metabolism, and breath hydrogen is derived from bacterial metabolism in the intestinal tract.[114] Following an oral dose of lactose, the disaccharide will normally be split into its constituent monosaccharides and absorbed. With lactase deficiency, unabsorbed disaccharide will pass into the large bowel and bacterial metabolism will produce hydrogen that is absorbed into the systemic circulation and exhaled in the breath. Breath hydrogen can be measured in end-expiratory breath using laboratory or hand-held direct-reading electrochemical hydrogen monitors.

BOX 48-3 Protocol for Lactose Tolerance Test With Measurement of Breath Hydrogen

Meal before 7 PM (restriction on wheat and fiber), then fasting until test completed
Brush teeth (night and morning) or use mouthwash
Measure end-expiratory fasting breath H_2
Give lactose solution (50 g in 180 mL water)
Rinse mouth with further 20 mL water and swallow
Measure breath H_2 at 15, 30, 60, 90, and 120 min
Test can be stopped if earlier rise of >20 ppm above fasting level

Patient Preparation. Appropriate patient preparation is essential to ensure stable baseline breath hydrogen levels (see Box 48-3). Avoidance of wheat-based foods and fiber for 12 hours before the test minimizes the availability of substrates for bacterial metabolism in the large bowel. Fasting breath hydrogen is typically <5 ppm (5 μL/L) and concentrations >20 ppm (20 μL/L) may be an indication of malabsorption or bacterial overgrowth.[141] Oral hygiene before ingestion of the substrate in hydrogen breath tests minimizes the production of hydrogen by oral bacteria. Brushing of teeth or use of an antibacterial mouthwash (e.g., 1% chlorhexidine) is recommended.[128] Mouthwash containing alcohol should not be used, because this may interfere in the measurement of hydrogen. Cigarette smoke contains high hydrogen levels and smoking is therefore not permitted immediately before or during the test.

After an overnight fast, a baseline breath hydrogen level is recorded and 50 g of lactose in 180 mL water is drunk, followed by a further 20 mL of water to rinse the mouth and further reduce the possibility of an early rise in breath hydrogen from the action of oral bacteria. The dose in children should be 2 g/kg up to a maximum of 50 g. Breath hydrogen is then measured at 15, 30, 60, 90 and 120 minutes.

Interpretation. Most publications indicate that an increase in breath hydrogen of >20 ppm (20 μL/L) above the baseline fasting concentration within 2 hours of ingesting the lactose is indicative of lactose malabsorption.[129,137] However, recent data suggest that a cut-off of 10 ppm (10 μL/L) improves diagnostic sensitivity without increasing the number of false-positive test results.[97] In most patients with normal lactose absorption, breath hydrogen levels will remain at 2 to 5 ppm throughout the test. Occasionally, high levels may occur within the first 30 minutes after lactose ingestion. This may indicate either very rapid transit of lactose to the cecum or bacterial metabolism in the small bowel because of bacterial overgrowth. Repeating the breath test with lactulose or glucose as the substrate or using imaging techniques to confirm transit time will normally clarify the cause of such results.

BOX 48-4 Abnormalities of the Small Intestine Associated With Bacterial Overgrowth

Jejunal diverticuli
Crohn's disease
Autonomic neuropathy
Scleroderma (systemic sclerosis)
Pseudo-obstruction
Postgastrectomy

In lactose malabsorption, breath hydrogen is typically elevated (30 to 100 ppm, 30 to 100 μL/L) at 60 to 120 minutes after lactose ingestion. In a few subjects, the large bowel bacteria do not produce hydrogen; in such patients a normal result does not exclude lactase deficiency. Very low hydrogen when fasting and throughout the test may therefore indicate a false-negative result. Some estimates suggest that up to 10% to 13% of the population have large bowel bacteria that do not produce hydrogen,[105] although others have found the prevalence of hydrogen nonproducers to be less than 2%.[129,163] Such false negatives can be confirmed by the failure to produce hydrogen at 45 to 180 minutes after ingestion of lactulose (10 g), which is a nonabsorbable disaccharide and therefore available for bacterial metabolism in the large bowel.

A positive breath hydrogen result following ingestion of lactose may also occur in glucose-galactose malabsorption, which also causes intestinal symptoms. When necessary, glucose-galactose malabsorption can be confirmed or excluded by a breath test in which 25 g each of glucose and galactose are substituted for 50 g lactose. An increase in breath hydrogen confirms the diagnosis.

Sucrose and Trehalose Tolerance Tests

Sucrase-isomaltase deficiency can be investigated by using 50 g sucrose instead of lactose. An increase in breath hydrogen of >20 ppm (20 μL/L) within 2 hours is diagnostic. It is rarely necessary to test for trehalase deficiency, although a breath test using 25 g trehalose has been described.[3]

Bacterial Overgrowth

The proximal small intestine (duodenum and jejunum) normally contains few bacteria. Most ingested bacteria do not survive the acidic environment of the stomach and therefore few live organisms normally enter the small bowel. The motility of the jejunum prevents fecal-type organisms from progressing up into the jejunum from the cecum. The ileum normally contains some fecal-type bacteria. Colonization of the upper small bowel is described as bacterial overgrowth and usually occurs as a consequence of other abnormalities (structural or motility disorders) of the small intestine (see Box 48-4). Use of PPIs is associated with an increased risk of bacterial colonization.

TABLE 48-6 Reported Sensitivity and Specificity of Lactulose and Glucose Hydrogen Breath Tests for the Diagnosis of Bacterial Overgrowth

Substrate	Increment Over Baseline*	Sensitivity	Specificity	Reference
Glucose 50 g	≥12 ppm	93	78	Kerlin and Wong 1988
Glucose 50 g	>10 ppm	78	89	Flourie et al 1989
Glucose 50 g	≥15 ppm	90	—	Stotzer and Kilander 2000
Glucose 75 g	≥10 ppm	62	83	Corazza et al 1990
Lactulose 12 g	>10 ppm	68	44	Corazza et al 1990

*1 ppm = 1 μL/L.

The bacteria colonizing the small bowel (such as *Escherichia coli* and *Bacteroides* species) deconjugate and dehydroxylate bile salts, leading to conjugated bile salt deficiency, which causes fat malabsorption. Bacterial metabolism of vitamin B_{12} may also occur, leading to vitamin B_{12} deficiency. The clinical symptoms of bacterial overgrowth are abdominal pain, diarrhea, and steatorrhea.[108]

The diagnostic gold standard requires intubation with aspiration of jejunal contents and the demonstration of a bacterial count of $>10^7$ organisms/mL and $>10^4$ anaerobes/mL.[61] In practice, hydrogen breath tests using either lactulose or glucose as substrates are used more frequently. An alternative diagnostic approach is to use a therapeutic trial of antibiotics.

For hydrogen breath tests, patient preparation is the same as that described in the previous section for the lactose breath hydrogen test. Lactulose (usually given in a dose of 10 g in 200 mL water) is a nonabsorbable disaccharide. In a normal subject, breath hydrogen does not increase until the lactulose enters the large intestine; the time from ingestion to a rise in breath hydrogen is therefore normally an indication of small bowel transit time. In bacterial overgrowth, there is an early rise in breath hydrogen of at least 20 ppm (20 μL/L) within 30 minutes of ingestion of lactulose. The early increase is diagnostic when it can be distinguished clearly from the later colonic rise. Frequent measurements (e.g., at 5-minute intervals) are essential in the first 30 minutes, with measurements every 15 minutes thereafter for up to 3 hours.[149]

Glucose is an alternative substrate; the usual adult dose is 50 g (as monohydrate) in 250 mL water.[100,179] An increase in breath hydrogen of >12 ppm (12 μL/L) above the fasting concentration indicates bacterial overgrowth. In bacterial overgrowth, breath hydrogen usually increases within 75 minutes of ingestion of glucose and sometimes within 30 minutes. The finding of an increased fasting breath hydrogen has high specificity for bacterial overgrowth but poor sensitivity; however, a fasting breath hydrogen >15 ppm and an increment of at least 12 ppm within 2 hours of a 50 g glucose challenge is diagnostic of bacterial overgrowth.[100,141] The high fasting breath hydrogen levels, even after adequate dietary preparation, are thought to be caused by stasis of gut contents or endogenous glycoproteins being used as substrates for hydrogen production by intestinal bacteria.[141] Table 48-6 compares some of the published data for diagnostic accuracy of tests using lactulose or glucose.

Variations in gastric emptying rate and small bowel transit times are problems that limit the diagnostic accuracy of the breath hydrogen tests. In the face of an appropriate clinical picture and a negative breath hydrogen test, an alternative diagnostic approach is a therapeutic trial of appropriate antibiotics.[4]

Other tests for bacterial overgrowth have used ^{14}C-xylose or ^{14}C-glycocholic acid.[105] When there is bacterial overgrowth, the bacteria deconjugate the glycocholic acid to produce ^{14}C-glycine that is absorbed and metabolized with an increase in breath $^{14}CO_2$. As in other tests, an early rise in the marker indicates either bacterial overgrowth or rapid transit to the large bowel where the normal colonic flora release ^{14}C-glycine. These tests using radioactive isotopes have largely been replaced by hydrogen breath tests that have comparable diagnostic performance and methodological advantages.[162]

Bile Salt Malabsorption[34]

Bile acids are synthesized in the liver and pass into the lumen of the small bowel via the gallbladder. Bile acids are present in bile as taurine or glycine conjugates; as the pH of bile is slightly alkaline and contains significant amounts of sodium and potassium, most of the bile acids and their conjugates exist as salts (i.e., bile salts). In practice, the terms bile acids and bile salts are frequently used as synonyms. Their major function is to act as surface-active agents, forming micelles and facilitating the digestion of triglycerides and the absorption of cholesterol and fat-soluble vitamins. Little reabsorption of bile acids occurs in the proximal small bowel, but normally >90% are reabsorbed in the terminal ileum. They return to the liver in the portal circulation and are resecreted

into the bile. This is known as the enterohepatic circulation. Less than 10% of secreted bile acids are lost in the feces, or about 0.2 to 0.6 g/day.

Bile acid malabsorption leading to chronic diarrhea occurs when there is ileal disease (e.g., Crohn's disease), or after resection of the terminal ileum; it may also occur following cholecystectomy and in some patients with irritable bowel syndrome.[160] The malabsorption of bile salts produces diarrhea by two different mechanisms. When significant bile salt depletion occurs, the deficiency of intraluminal bile salts leads to fat malabsorption and steatorrhea. More commonly, malabsorption of bile salts in the ileum leads to increased concentrations of bile salts in the colon where they alter water and electrolyte absorption. This leads to net secretion of water into the lumen and diarrhea. Bile salt malabsorption is probably an underdiagnosed condition and should be suspected in patients with unexplained chronic diarrhea.[156,171,183]

Three different procedures have been used to make a diagnosis of bile salt malabsorption—the ^{75}selenohomocholyltaurine test, measurement of serum 7α-hydroxy-4-cholesten-3-one in serum, and a therapeutic trial of bile acid sequestrants such as cholestyramine. The most widely used test involves the oral administration of the synthetic radioactive bile acid ^{75}selenohomocholyltaurine (^{75}SeHCAT). Following the dose, whole body gamma counting is carried out to estimate the basal level at 1 hour (100%). The gamma count is measured again after 7 days, when normally >15% of the administered dose is retained. Retention of <10% indicates bile salt malabsorption. Patients with <5% retention of ^{75}SeHCAT often have a good response to treatment with bile acid sequestrants.

Measurement of 7α-hydroxy-4-cholesten-3-one has been proposed as a simpler alternative to ^{75}SeHCAT. Evidence indicates that the fasting serum level of this intermediary between cholesterol and taurocholic acid reflects the activity of hepatic cholesterol 7α-hydroxylase and therefore the rate of bile acid synthesis. Bile acid malabsorption is associated with increased serum concentrations of 7α-hydroxy-4-cholesten-3-one as hepatic synthesis increases to maintain the pool of circulating bile acids.[5] A good correlation has been demonstrated between serum 7α-hydroxy-4-cholesten-3-one and results of the ^{75}SeHCAT test.[51] Two subsequent publications on patients with chronic diarrhea have documented the high sensitivity of the measurement for identifying those with bile acid–induced diarrhea.[14,151] The test has been compared with ^{75}SeHCAT and with the response to cholestyramine. The latter avoids the problems of assuming 100% sensitivity and specificity for the ^{75}SeHCAT test. Using the therapeutic response to cholestyramine as the "gold standard," the positive predictive value of serum 7α-hydroxy-4-cholesten-3-one increased to 74% (from 71%) and the negative predictive value increased to 98% (from 94%).

With the growing awareness of the likely role of bile salt malabsorption in the chronic diarrhea of a proportion of patients with irritable bowel syndrome and the therapeutic effectiveness of cholestyramine,[156,160] the measurement of serum 7α-hydroxy-4-cholesten-3-one, with its high negative predictive value, could be used to exclude bile salt malabsorption. High concentrations would be confirmed by a follow-up ^{75}SeHCAT test or a therapeutic trial with cholestyramine.

Protein-Losing Enteropathy

Loss of significant amounts of serum proteins into the bowel lumen and their passage in the feces is a consequence of a wide range of GI disorders. These may be associated with inflammation or ulceration of a segment of the small or large bowel (as in Crohn's disease and ulcerative colitis) or stomach, with diseases in which the intestinal lymphatics are obstructed or where there is elevated lymphatic pressure (e.g., lymphoma and Whipple's disease), or with disorders associated with altered immune status, such as systemic lupus erythematosus and some food allergies.

In the healthy bowel, fecal protein is largely derived from enterocytes shed from the mucosal surface and from intestinal secretions. The normal GI loss of albumin is less than 10% of albumin catabolism, representing a daily loss of less than 1% to 2% of the serum protein pool.[104] Protein loss may be greatly increased in disease. In studies using ^{51}Cr-labeled proteins, 0.1% to 0.7% of an injected dose was excreted in feces over 4 days in healthy subjects; in protein-losing enteropathies this may increase to 40%, leading to hypoalbuminemia and edema.

The diagnosis of protein-losing enteropathy should be considered in the investigation of patients with hypoalbuminemia in whom renal loss, liver disease, and malnutrition have been excluded. The classical test for the diagnosis of protein-losing enteropathy is the measurement of fecal ^{51}Cr-albumin following an intravenous injection, although it is now rarely available. Imaging techniques that seek to detect the specific site of the protein loss have also been described using either ^{99m}Tc-human serum albumin or ^{99m}Tc-dextran.

The fecal clearance of alpha-1-antitrypsin (AT) can also be used as a marker of GI protein loss. AT is a glycoprotein (MW 54,000) that is synthesized in the liver and is normally present in the serum at a concentration of about 1.5 to 2 g/L. It is a protease inhibitor and therefore resistant to degradation by proteolytic enzymes in the GI tract. The fecal clearance of AT correlates with protein loss measured by ^{51}Cr techniques ($r = 0.96$).[60] The correlation is not influenced by serum AT concentrations or by fecal weight. AT clearance can be used for both small and large bowel disease and is applicable to the evaluation of enteric protein loss in children or adults.[60,82] More recent work has confirmed these findings and also confirmed that fecal AT concentration alone does not reliably predict AT clearance (i.e., a timed fecal sample and measurement of serum AT is required).[164] An important observation is that experimentally induced diarrhea in normal subjects leads to an increased AT clear-

ance. The mechanism is unclear but could be related to a decreased time for degradation of AT if intestinal transit time is shorter. The upper limits of the reference interval (estimated as mean + 2SD) were found to be 56 mL/day and 24 mL/day in normal subjects with and without diarrhea, respectively. In inflammatory bowel disease, AT clearance may be as high as 200 mL/day, which represents a loss of about 6 g albumin/day.[164] The AT clearance must be interpreted with caution in patients with positive fecal occult blood tests, as the blood loss might be sufficient to falsely increase the AT clearance. Measurement of fecal AT has been suggested as an alternative to fecal occult blood for the detection of colorectal cancer.[131] AT is rapidly destroyed in gastric juice (and in vitro) when the pH is below 3.0, which has meant that the test can only be used to assess protein loss distal to the pylorus.[60] However, administration of PPIs can be used to inhibit gastric acid secretion before collection of the fecal sample, thereby enabling assessment of protein loss from the stomach.[167]

A recent study evaluated the use of AT clearance as a marker of clinical relapse in patients with Crohn's disease and showed a negative predictive value of 94% for predicting relapse in the next 6 months (at a cut-off of 120 mL/day). Sensitivity was only 50% and comparable results were noted when the Bristol Simple Index score was used to predict relapse so that at present the test appears to have little clinical value in this context.[10]

AT in feces and serum can be measured most conveniently by radial immunodiffusion. Feces should be collected quantitatively, preferably for 3 days, in preweighed containers and kept refrigerated. The AT is extracted into saline before analysis. AT clearance is calculated as follows:

$$\text{AT clearance (mL/day)} = \frac{(\text{fecal weight} \times \text{fecal AT concentration})}{\text{serum AT}}$$

where fecal weight is expressed in g/day, fecal AT in mg/kg feces, and serum AT in mg/L.

THE PANCREAS: DISEASES AND ASSESSMENT OF EXOCRINE PANCREATIC FUNCTION

It will be evident from the section on processes of digestion and absorption that the pancreas plays a central role in the absorptive process for carbohydrates, fats, and proteins. Disorders of the exocrine pancreas are therefore frequently associated with GI symptoms of malabsorption or diarrhea. In this section, pediatric and adult exocrine pancreatic disorders are briefly discussed and tests for assessing exocrine pancreatic function are described. Information on exocrine pancreatic tumors can be found in the later section on GI regulatory peptides. Recent textbooks on gastroenterology or medicine have more detail on the clinical aspects of exocrine pancreatic disorders.[17,62]

BOX 48-5 The Spectrum of Pancreatic Disease in Childhood

Disorders of morphogenesis
- Annular pancreas, pancreas divisum, pancreatic hypoplasia and agenesis, heterotopic pancreas

Inherited syndromes affecting the pancreas
- Cystic fibrosis
- Shwachman-Diamond syndrome, Johnson-Blizzard syndrome, Pearson bone marrow pancreas syndrome

Gene mutations leading to pancreatic disease
- Hereditary pancreatitis; cationic trypsinogen gene mutations, trypsin inhibitor gene mutations

Pancreatic insufficiency syndrome
- Isolated enzyme deficiencies, lipase, colipase, enterokinase

Pancreatic insufficiency secondary to other disorders
- Celiac disease

Acquired pancreatitis in childhood
- Idiopathic, traumatic, drugs, viral, metabolic, collagen vascular diseases, autoimmune, fibrosing, nutritional (tropical)

PEDIATRIC DISORDERS OF THE EXOCRINE PANCREAS

Pancreatic disorders in childhood have recently been reviewed[29] and are summarized in Box 48-5.

Cystic fibrosis (CF) is the most common severe autosomal recessive disease, with an estimated gene frequency in Western Europe and the United States of between 1:25 and 1:35 and a disease incidence of about 1 in 2500 to 1 in 3200. The pathogenesis and diagnosis of CF are described in Chapter 40. Pancreatic insufficiency is present at birth in 65% of infants with CF, and a further 15% develop it during infancy and early childhood. The 20% who do not develop pancreatic insufficiency have a better prognosis and develop fewer complications.

The measurement of pancreatic elastase-1 in feces (see section on noninvasive tests of exocrine pancreatic function) is considered to be a reliable test for pancreatic insufficiency in infants over the age of 2 weeks with CF and in older children at diagnosis of the disorder.[19,113,143] The test can also be used to detect the onset of pancreatic insufficiency in those previously pancreatic sufficient.

ADULT DISORDERS OF THE EXOCRINE PANCREAS

The major exocrine pancreatic disorders presenting in adult life are acute pancreatitis, chronic pancreatitis, and carcinoma of the pancreas.[62] The use of enzyme tests in the diagnosis of acute pancreatitis is discussed in Chapter 21. The etiologies of pancreatitis are given in Box 48-6.

Chronic pancreatitis is defined by irreversible pancreatic damage with histological evidence of inflammation and fibrosis leading to destruction of both endocrine and exocrine function. There are many causes of chronic pancreatitis but the major histological features are similar

BOX 48-6 Etiologies of Pancreatitis in Adults

Acute
- Gallstones
- Alcohol
- Infections, e.g., mumps, Coxsackie B
- Pancreatic tumors
- Drugs, e.g., azathioprine, estrogens corticosteroids
- Iatrogenic (e.g., postsurgical, ERCP)
- Hyperlipidemias
- Miscellaneous—trauma, scorpion bite, cardiac surgery
- Idiopathic

Chronic
- Alcohol
- Tropical (nutritional)
- Hereditary (trypsinogen and inhibitory protein defects, cystic fibrosis membrane regulator [CFTR] defects)
- Idiopathic
- Trauma
- Hypercalcemia

BOX 48-7 Pancreatic Imaging Procedures

A plain abdominal radiograph:
May show pancreatic calcification, particularly when alcohol is the etiology.

Ultrasound:
A useful screening investigation for inflammation and neoplasia. Views may be limited by overlying bowel gas.

Spiral CT:
With contrast enhancements is more reliable.

MRI scanning:
An alternative to CT. Magnetic resonance cholangiopancreatography (MRCP) gives clear definition of the pancreatic duct and the biliary tree. Gallstones (including microcalculi) may also be identified in the biliary tree using MRI/MRCP.

Endoscopic ultrasound:
Very useful for identifying distal common bile duct stones and microcalculi within the duct or within the gallbladder. Small space-occupying lesions may also be identified.

Endoscopic retrograde cholangiopancreatography (ERCP):
This has been considered a gold standard modality for defining pancreatic disease. However, with improving imaging technique, ERCP is now more likely to be restricted to therapeutic intervention.

From Burroughs AK, Westaby D. Liver, biliary tract disease and pancreatic disease. In: Kumar P, Clark M, eds. Clinical medicine, 5th ed. Edinburgh: WB Saunders, 2002:395-404.

regardless of the cause. In Western countries, the most common cause is alcohol (60% to 90% of all cases of chronic pancreatitis), although as only 5% to 15% of heavy drinkers develop the disease, there are clearly other predisposing factors (e.g., smoking, diets high in fat and protein).

The role of invasive and noninvasive tests of pancreatic exocrine tests in chronic pancreatitis has recently been reviewed.[65]

Tests of Exocrine Function of the Pancreas

The predominant exocrine functions of the pancreas are the production and secretion of pancreatic juice, which is rich in enzymes and bicarbonate. Normal pancreatic juice is colorless and odorless; it has a pH of 8.0 to 8.3 and a specific gravity of 1.007 to 1.042. The total 24-hour secretion volume may be as high as 3000 mL.[150]

A number of laboratory tests are available to measure exocrine function in the investigation of pancreatic insufficiency (most commonly caused by cystic fibrosis in children and chronic pancreatitis in adults). Tests fall into two categories, invasive and noninvasive. Invasive tests require GI intubation to collect pancreatic samples; noninvasive tests (or "tubeless tests") were developed to avoid intubation, which is uncomfortable for the patient, time-consuming, and therefore expensive. Noninvasive tests are simpler and cheaper to perform, but in general they lack the sensitivity and specificity of the invasive tests, particularly for the diagnosis of mild pancreatic insufficiency. It is important to recognize that biochemical tests have a limited clinical application in the diagnosis of pancreatic disease because of either the complexity of the invasive tests or the inadequate sensitivity and specificity for mild and moderate pancreatic disease of the noninvasive tests. Of greater importance are the imaging procedures (see Box 48-7). These techniques continue to be developed. A recent study shows that administration of secretin, causing stimulation of fluid and bicarbonate secretion, leads to anatomical changes that can be quantified by magnetic resonance cholangiopancreatography, with significant differences between normal volunteers and patients with pancreatic insufficiency.[32] In the future, it may therefore be possible to confidently diagnose pancreatic insufficiency by imaging techniques alone.

Invasive Tests of Exocrine Pancreatic Function

The main types of invasive tests are summarized in Table 48-7.

Total volume of pancreatic juice, amount or concentration of bicarbonate, and activities of pancreatic enzymes are measured in duodenal contents. The enzyme most commonly measured is trypsin, but amylase, lipase, chymotrypsin, and elastase may also be evaluated. The *Lundh test* consists of administering a standardized meal consisting of 5% protein, 6% fat, 15% carbohydrate, and 74% nonnutrient fiber. Advantages of the Lundh meal are that it provides a physiological stimulus to the pancreas and is simple to administer. However, administration of the meal prevents determination of the total enzyme and bicarbonate or secretory volume. Moreover, it provides inadequate or no stimu-

TABLE 48-7 Summary of Invasive Tests of Pancreatic Exocrine Function

Procedure	Pancreatic Stimulant	Analysis of Duodenal Contents
Lundh test	Standardized meal	Enzyme output
Secretin stimulation test	Purified or synthetic porcine secretin	Bicarbonate output
Secretin-cholecystokinin (CCK) test	Secretin as above plus CCK analogue (CCK-8 or ceruletide)	Bicarbonate and enzymes

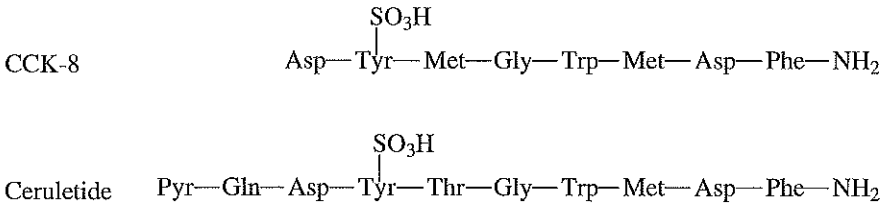

Figure 48-7 Comparison of amino acid sequences of CCK-8 and ceruletide.

lation in the presence of mucosal diseases, such as celiac disease, in which hormone release from the duodenal mucosa is impaired. In view of these limitations, the Lundh test is largely of historical interest.

The *secretin test* is based on the principle that secretion of pancreatic juice and bicarbonate output are related to the functional mass of pancreatic tissue. After an overnight fast, basal samples of fluid are collected from the stomach and duodenum. One clinical unit (CU) of secretin/kg body weight is administered intravenously, and duodenal fluid is collected at 15-minute intervals for at least 1 hour. Purified porcine secretin has traditionally been used for the test, but recent studies have confirmed that synthetic porcine secretin (0.2 μg/kg) gives results that are not significantly different from results with biologic secretin.[159]

Secretin stimulates the secretion of pancreatic juice and bicarbonate, but stimulation of the secretion of pancreatic enzymes is inconsistent. Addition of CCK (or a synthetic equivalent) to the secretin stimulation test provides a stimulus to the secretion of pancreatic enzymes, allowing a more complete assessment of pancreatic reserve than can be obtained with secretin alone. The functional activity of CCK resides in the C-terminal octapeptide sequence (CCK-8), and either this octapeptide or ceruletide (a synthetic decapeptide identical to the natural decapeptide cerulein) can be used to stimulate pancreatic enzyme secretion (Figure 48-7).

The procedure for the secretin-ceruletide test is similar to that described for the secretin test. Patients are required to fast overnight; they are then intubated with a gastroduodenal tube placed into the duodenum under x-ray control. After collecting basal fluid for 15 minutes, 1 U secretin/kg body weight/hr is continuously given intravenously for 2 hours; 30 mg ceruletide/kg body weight/hr is given simultaneously for the second hour. Pancreatic juice is collected during 15-minute intervals, and volume, pH, bicarbonate, and enzymes are measured.[120] Procedures and reference values are not standardized among laboratories. It is recommended that doses of secretagogues should be high enough to provide maximal pancreatic stimulation and given for at least 60 to 90 minutes to ensure better diagnostic accuracy, especially in mild pancreatic insufficiency.[65]

Noninvasive Tests of Exocrine Pancreatic Function

"For many years, gastroenterologists have searched for the holy grail of pancreatic function tests—the tubeless test."[39] Not surprisingly, a range of tests has been proposed, but none has adequate sensitivity for reliably detecting early pancreatic disease. When malabsorption is present, such tests are of value in confirming or excluding pancreatic disease. Considerable overlap often occurs between results observed in normal individuals and those found in patients with pancreatic disorders, which is mainly due to the large functional reserve of the pancreas. An estimate has been made that pancreatic insufficiency cannot clearly be demonstrated until at least 50% of the acinar cells have been destroyed. Clinical signs of pancreatic insufficiency often do not appear until the destruction of 90% of acinar tissue. In general, the noninvasive (tubeless) tests may therefore be used when investigating causes of malabsorption but have inadequate sensitivity for the diagnosis of chronic pancreatitis. Comparison between studies and of different markers is difficult because the "gold standard" may be either functional tests, which may differ in procedure and reference values,[111,120,161] or morphological assessment. In some cases a direct comparison of one noninvasive test with another has been made. Table 48-8 compares the diagnostic performance of noninvasive tests.

The principle of the *amino acid consumption test* is that stimulation of the pancreas by CCK increases the uptake of

TABLE 48-8 Diagnostic Accuracy of Noninvasive Tests for Mild, Moderate, and Severe Pancreatic Insufficiency, as Assessed by Anatomical or Functional Criteria

	Sensitivity for Pancreatic Insufficiency			
Test	**Mild**	**Moderate**	**Severe**	**Specificity**
Amino acid consumption test[71]	"... unsuitable for clinical use"			
Fecal chymotrypsin[70]	11%	54%	77%	85%
Fecal elastase-1[70]	22%	77%	100%	96%
NBT-PABA[63,138]	—	50%	70%	72%
Pancreolauryl[39,138]	<50%	50%	85%	50%
^{13}C-MCT absorption[119]	62%	—	100%	85%

amino acids from the plasma, leading to greater depletion of plasma amino acids in normal subjects compared with patients with pancreatic insufficiency. Despite initially promising results, the test is now considered unsuitable for clinical use because of low specificity.[71]

All of the other noninvasive tests are based on the reduction in the secretion of pancreatic enzymes with direct measurement of enzymes in feces (chymotrypsin or elastase) or detection of products of their catalytic reactions, after oral administration of synthetic substrates, in urine (NBT-PABA or pancreolauryl test) or in breath (^{13}C-mixed chain triglyceride breath test).

Pancreatic chymotrypsin is almost completely digested during its passage through the gut in adults, but the residual activity of the enzyme in feces is stable for several days at 20 °C. Its output in stool correlates poorly with chymotrypsin secretion in duodenal contents when both are measured after stimulation with secretin-CCK. In patients without pancreatic disease, the incidence of falsely low results is about 10% to 15% and may be due to (a) voluminous stools (>300 g/day) and thus less enzyme per gram of feces; (b) inadequate food intake; (c) partial gastrectomy or mucosal disease (e.g., celiac disease), which causes inadequate stimulation of pancreatic secretion; or (d) obstruction of the bile duct. Falsely normal results in patients with mild pancreatic insufficiency may be as high as 50%.[72] In a recent collaborative study in children, both fecal chymotrypsin and elastase showed 100% sensitivity for detecting pancreatic insufficiency in cystic fibrosis, but the specificity of chymotrypsin was lower than that of elastase in a control group of children with small intestinal diseases.[21] Most recent papers conclude that although chymotrypsin measurement is easier than elastase measurement, the latter test has significant advantages in diagnostic accuracy. The recommended procedure[98] uses a stool pretreatment stage that dissociates particle-bound chymotrypsin. The method is simple and fast and is available as a reagent kit supplied by Roche Diagnostics GmbH, Mannheim, Germany. Sample is extracted with a mixture of salts and a detergent, lauryltrimethylammonium chloride, which fully dissociates the enzyme from particles in stool. The extract is mixed with a synthetic substrate, a pentapeptide of 4-nitroaniline (4-NA); the substrate is hydrolyzed by chymotrypsin to produce free 4-NA. Continuous release of 4-NA is measured photometrically at 405 nm.

TABLE 48-9 Comparison of Fecal Chymotrypsin and Elastase

	Fecal Enzyme	
	Chymotrypsin	**Elastase**
10 day intraindividual variation (mean CV)	30%	15%
Loss of activity (7 days at 4 °C)	17%	2.5%
Overall diagnostic sensitivity	64%	93%
Overall diagnostic specificity	89%	93%

Loser C, Mollgaard A, Folsch UR. Faecal elastase 1: a novel, highly sensitive, and specific tubeless pancreatic function test. Gut 1996;39: 580-6.

Pancreatic elastase-1 is a pancreas-specific protease present in the pancreatic juice. It is not degraded during passage through the gut and concentrations in feces are fivefold to sixfold greater than those in pancreatic juice.[166] The enzyme can be determined in feces with a commercial ELISA assay that uses two monoclonal antibodies specific to the human enzyme (Schebo-Tech, Wettenberg, Germany). Treatment of patients with pancreatic enzyme supplements does not therefore interfere with the test (Figure 48-8). Table 48-9 compares chymotrypsin and elastase, indicating some of the advantages of fecal elastase measurement.

Fecal elastase-1 has been extensively evaluated both in cystic fibrosis and in adult pancreatic insufficiency. In children with cystic fibrosis, the test discriminates between those with and without pancreatic insufficiency.[70] Very low elastase-1 is seen in a wide range of *CFTR* genotypes with undetectable enzyme (<15 μg/g of stool) in most ΔF508 homozygotes.[143,178] Low fecal elastase (<200 μg/g) after 4

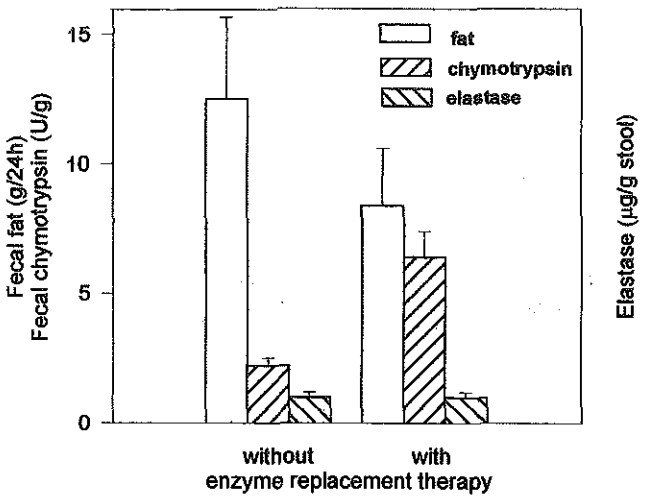

Figure 48-8 Fecal excretion (mean and SD) of chymotrypsin, fat, and immunoreactive elastase during a 24-hour collection period in 12 patients with cystic fibrosis and steatorrhea with and without enzyme replacement therapy. *(From Stein J, Jung M, Sziegoleit A, Zeuzem S, Caspary WF, Lembcke B. Immunoreactive elastase I: clinical evaluation of a new non-invasive test of pancreatic function. Clin Chem 1996;42:222-6.)*

weeks of age is indicative of pancreatic insufficiency and provides supporting evidence for a diagnosis of cystic fibrosis.[19]

The test has been evaluated in adults against the secretin-cerulein test[111,120,161] and in patients whose diagnosis of chronic pancreatitis has been made on the basis of anatomical and morphological changes detected by ultrasound and endoscopic retrograde pancreatography or computerized tomography.[40,72,127] The test is routinely carried out on a small random fecal sample, which might be expected to give inferior diagnostic accuracy to those evaluations carried out on portions of 24-hour or 72-hour fecal collections. However, with random fecal samples, specificities of 98% and 100% have been reported in healthy controls and specificities of 90% to 97% in patients with nonpancreatic GI disease. Positive results (i.e., <200 µg/g) have been reported in patients with clinical or laboratory evidence of malnutrition who also have inflammatory bowel disease or chronic diarrhea (nonpancreatic). These observations may actually be due to impaired pancreatic secretion as a consequence of malnutrition.[127] The authors also suggested that increased bacterial degradation of the enzyme might be the cause of false positives in some patients with bacterial overgrowth. Similar results have been reported in children with nonpancreatic disease; the finding of a low fecal elastase in a child with steatorrhea probably indicates coexisting pancreatic insufficiency.[21]

Measurement of pancreatic elastase-1 in feces has high sensitivity for the detection of severe and moderate chronic pancreatitis in adults. It has better sensitivity than other tests for detecting mild chronic pancreatitis and high sensitivity and high negative predictive value for discriminating between diarrhea of pancreatic and nonpancreatic origins. The test is not specific for pancreatitis and detects moderate to severe impairment of pancreatic exocrine secretion from any cause. It is considered to be the most suitable test to confirm pancreatic insufficiency in screened cystic fibrosis infants over the age of 2 weeks,[19] and as previously noted the test result is not influenced by the administration of pancreatic enzyme supplements.

The *NBT-PABA test* of pancreatic function is based on the hydrolysis, by chymotrypsin, of a synthetic tripeptide—*N*-benzoyl-l-tyrosyl-p-aminobenzoic acid. The tripeptide, variously called NBT-PABA, BTP, or bentiromide, is administered orally together with a test meal to stimulate pancreatic secretion. BTP is specifically hydrolyzed by chymotrypsin in the duodenum to release PABA, which is subsequently absorbed in the intestinal tract and metabolized in the liver to hippurate and to PABA glucuronide and PABA acetylate. These arylamines are then excreted by the kidney. In the presence of low chymotrypsin, as found in pancreatic insufficiency, less peptide is hydrolyzed, and therefore less chromogen is excreted in the urine or found in serum. Thus the amount of PABA detected in serum or urine is an indirect measure of chymotrypsin activity in duodenal content.

Test results are affected by defective intestinal absorption caused by intestinal disease or variations in transit time, by impaired hepatic conjugation caused by liver disease, and by impaired renal excretion. To compensate for these possible errors, a "control" substance (e.g., PABA) may be given on a second day, or alternatively, ^{14}C-PABA or p-aminosalicylic acid (PAS) can be given orally with the NBT-PABA. Low recovery of the control substance in the urine indicates probable decreased intestinal absorption or decreased renal excretion. About 60% (range 48% to 72%) of the orally administered dose is recovered in the urine normally. In pancreatic insufficiency, PABA excretion is significantly decreased. The result is then calculated as a "pancreatic excretion index" (PEI) as follows:

$$\text{PEI} = \frac{\text{test substance in urine} \times 100}{\text{control substance in urine}}$$

The specificity of the test was significantly improved by abandoning the nonspecific colorimetric procedures in favor of high-performance liquid chromatography (HPLC).[8,83] NBT-PABA has advantages over the pancreolauryl test in that the patient procedure can be completed in a single day; but the synthetic peptide is not now easily available, and the test has a lower diagnostic sensitivity and specificity for pancreatic insufficiency than does fecal elastase (see Table 48-8).

The *pancreolauryl test* (fluorescein dilaurate test, Temmler Pharma, Germany) is similar in its principle to the NBT-PABA test. Fluorescein dilaurate (FDL) is poorly water-soluble. It is given orally in the middle of a standard "breakfast" (50 g white bread, 20 g butter, and one cup of tea) and is specifically hydrolyzed by pancreatic cholesterol esterase, which requires bile salts for its activity. The released

fluorescein is water-soluble, readily absorbed by the small intestine, conjugated in the liver, and excreted in the urine. Urine is collected for 10 hours; an adequate urinary output is imperative and is assured by a 1.5 L fluid intake during the early part of the test. The test is repeated on a second day using free fluorescein to correct for individual variability in intestinal absorption, hepatic conjugation, and urinary excretion. The urinary recovery of fluorescein is measured on a spectrophotometer each day at 492 nm after hydrolysis with 0.1 mol/L sodium hydroxide under standard conditions. A pancreatic excretion index is calculated as described for the NBT-PABA test; normal pancreatic function is indicated by PEI >30%. Pancreatic insufficiency is indicated by a PEI of <20%; values between 20% and 30% are considered inconclusive. Urines with glucose >20 g/L (2 g/dL) can give misleading results with falsely increased PEI values. Similar errors may occur when serum fluorescein is measured in samples with serum glucose >14 mmol/L (~250 mg/dL). The effect of glucose can be avoided by carrying out the hydrolysis step at 60 °C.[175]

The FDL test produces results very similar to those obtained with the PABA test, although there is now general agreement that the sensitivity is higher than that of the PABA test (see Table 48-8). Analytically, measurement of fluorescein is simple, and good agreement between laboratories has been found from external quality assessment (EQA) results for measurements of fluorescein in urine.[45] The test results can also be expressed as peak serum fluorescein concentration; high sensitivity (100%) has been reported in moderate and severe chronic pancreatitis. The serum test has poor specificity in small bowel diseases because of the influence of factors other than pancreatic enzyme hydrolysis on the absorption of fluorescein.[40] Liver diseases are associated with false-positive results because bile salts are necessary for the digestion and absorption of the FDL.

A modification of the test has been the use of mannitol as a control marker, which can then be administered together with the FDL, enabling the patient procedure to be completed within 1 day. Urine was collected from 2 to 8 hours and the ratio of fluorescein to mannitol recoveries calculated. A clear separation between healthy controls and children with cystic fibrosis was obtained regardless of whether or not they were on enzyme replacement therapy.[68]

A number of different ^{13}C breath tests have been proposed for the evaluation of fat absorption[112]; most of them assess the overall ("global") process of fat absorption and are not able to differentiate fat malabsorption from pancreatic and nonpancreatic causes.

The ^{13}C-mixed chain triglyceride test is designed as a test of intraluminal pancreatic lipase activity.[177] The substrate for the test is 1,3-distearyl,2(carboxyl-^{13}C) octanoyl glycerol, which contains long chain fatty acids in positions 1 and 3 and the ^{13}C-labeled medium chain fatty acid (octanoic acid) in position 2 (Figure 48-9). The labeled substrate is administered orally to fasting patients with a standard meal of toast and butter. Breath samples are collected over a 5-hour

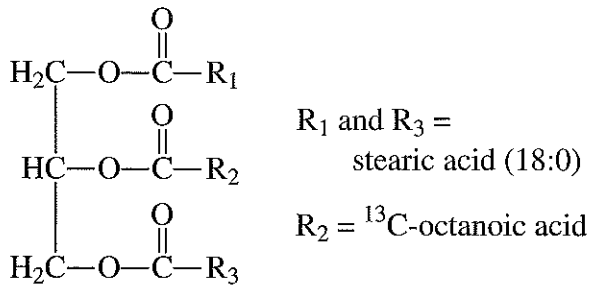

Figure 48-9 The substrate for the ^{13}C-mixed chain triglyceride breath test: 1,3 distearyl,2(carboxyl-^{13}C) octanoyl glycerol.

period, and exhaled $^{13}CO_2$ is expressed as a percentage of the administered dose. The rationale of the procedure is that before absorption or metabolism of the ^{13}C-octanoate, or ^{13}C-octanoyl monoglyceride, the stearyl groups must be hydrolyzed by the activity of pancreatic lipase. Decreased pancreatic lipase secretion will therefore lead to a reduction in the amount of ^{13}C label absorbed and subsequently metabolized to $^{13}CO_2$.

In an initial assessment, a group of 25 normal control subjects were compared with 29 patients with pancreatic disease. $^{13}CO_2$ in breath (cumulative over 6 hours) was highly correlated with pancreatic lipase output (Figure 48-10). The test was superior to the estimation of fecal fat for detecting impaired pancreatic function. Sensitivity and specificity were 89% and 81%, respectively. In a later evaluation, the test was compared with results from the secretin-cerulein test, with patients categorized as having mild (n = 13) or severe (n = 13) pancreatic insufficiency.[119] Fecal elastase and chymotrypsin were also measured. Fecal elastase and the ^{13}C-mixed chain triglyceride test both detected all cases of severe pancreatic insufficiency, but sensitivity was higher for fecal elastase in those with mild disease (see Table 48-8). Similar results were obtained when cholesteryl ^{13}C-octanoate was used as a substrate for a noninvasive test of pancreatic function.[27]

The sensitivity and specificity of these tests are limited by the complexity of the processes of absorption and metabolism. The substrates are specific for pancreatic lipases and the product is absorbed independently of micelle formation, but the results of the test are affected by other factors, such as gastric emptying, mucosal absorption, hepatic metabolism, endogenous $^{13}CO_2$, and total CO_2 production.[1,43] These factors may explain the test's limited diagnostic sensitivity in mild and moderate pancreatic insufficiency and its lack of specificity in nonpancreatic GI diseases.

Fecal elastase (measured by the monoclonal antibody method) remains the test of choice as a noninvasive test for assessing pancreatic insufficiency from the perspectives of both diagnostic accuracy and patient convenience. A negative test does not exclude mild disease, and false positives in some nonpancreatic diseases and in very watery samples limit

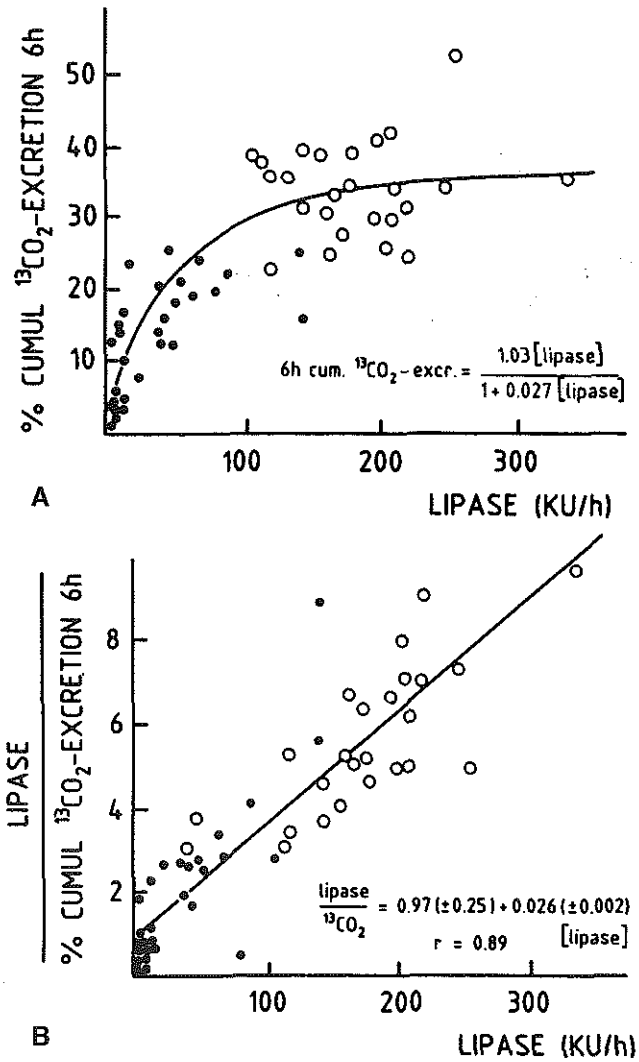

Figure 48-10 A, Cumulative $^{13}CO_2$ excretion (in percentage of ingested dose) 6 hours after intake of the [^{13}C]-labeled mixed triglyceride as a function of lipase activity (in kilounits per hour) in normal subjects (○) and patients with pancreatic disease (●). **B,** Linearly modified saturation curve following the relation given by the equation: Lipase/$^{13}CO_2$ = (1/A + B/A)(lipase), normal subjects (○), patients with pancreatic disease (●). *(From Vantrappen GR, Rutgeerts PJ, Ghoos YF, Hiele MI. Mixed triglyceride breath test: a noninvasive test of pancreatic lipase activity in the duodenum. Gastroenterology 1989;96:1126-34, with permission from the American Gastroenterological Association.)*

its diagnostic accuracy. A new ELISA based on polyclonal antibodies (and also called a test for "elastase 1") appears to have binding characteristics different from those of the monoclonal antibody assay and requires further evaluation.[75]

GI REGULATORY PEPTIDES

The gut is the largest endocrine organ in the body[148]; it is also a major target for many hormones, released locally and from other sites. GI regulatory peptides are released from the pancreatic islets (e.g., somatostatin) or from endocrine cells within the gut mucosa (e.g., cholecystokinin). Many of these peptides (such as VIP and somatostatin) are present in the enteric nerves and are also found in the central nervous system and have important roles in the neuroendocrine control of the gut. Although many of them (such as secretin and gastrin) fulfill the classic criteria for a hormone by acting on distant cells (see Chapter 28), others function as neurotransmitters or have local (paracrine) effects on adjacent cells. Collectively, they influence motility, secretion, digestion, and absorption in the gut. They regulate bile flow and secretion of pancreatic hormones and affect tonicity of vascular walls, blood pressure, and cardiac output.

There is a growing understanding of the role of the neuroendocrine system and gut peptides, and of the importance of the gut-hypothalamic pathway, in the normal control of food intake, and of the possibility of disorders in these mechanisms as causes of obesity.[152] The gastric peptide ghrelin and cholecystokinin act as short-term regulators of appetite and satiety. The neuropeptide PYY_{3-36}, a member of the neuropeptide Y family, is secreted by endocrine cells in the distal small intestine and colon in response to the ingestion of food. Recent evidence shows that infusion of PYY_{3-36} to physiological plasma concentrations in humans significantly decreases appetite with a 33% reduction in food intake over 24 hours. In mice, the relevant pathway is via the arcuate nucleus of the hypothalamus.[7] PYY_{3-36} is therefore a further addition to a growing list of hormones with a role in the regulation of energy balance.

Table 48-10 summarizes basic chemical characteristics of five of the major GI regulatory peptides and indicates their site of origin and major functions. More detailed descriptions of these five peptides are given below, followed by a listing of other regulatory peptides of the GI tract in Table 48-11.

CHOLECYSTOKININ[130,148]

CCK is a linear polypeptide that exists in multiple molecular forms. The first form isolated was the 33–amino acid peptide CCK-33. Other major forms are CCK-8, CCK-39, and CCK-58. In all forms, the five C-terminal amino acids are identical to those of gastrin and are necessary, together with a sulfated tyrosyl residue, for physiological activity. All of the forms of CCK are produced by enzymatic cleavage of a single 115–amino acid precursor, preprocholecystokinin.

CCK is found in the I cells of the upper small intestinal mucosa. Mixtures of polypeptides and amino acids (especially tryptophan and phenylalanine) stimulate CCK secretion, whereas pure undigested protein does not elicit a response. Secretion is also stimulated by gastric acid entering the duodenum and by fatty acids with chains of nine or more carbons, especially in the form of micelles. Circulating concentrations of CCK are therefore increased following ingestion of a mixed meal. CCK is rapidly cleared from plasma ($t_{1/2}$ = <3 min), predominantly by the kidneys. Secretion of CCK is completely inhibited after somatostatin infusion.

TABLE 48-10 Characteristics of Prominent Forms of Principal Gut Regulatory Peptides

Hormone/Peptide	Molecular Weight	No. of Amino Acids	Main Gut Localization	Principal Physiological Actions
Gastrin Family				
Cholecystokinin	3918	33 (also 385, 59)	Duodenum and jejunum Enteric nerves	Stimulates gallbladder contraction and intestinal motility; stimulates secretion of pancreatic enzymes, insulin, glucagon, and pancreatic polypeptides; has a role in indicating satiety; the C-terminal 8–amino acid peptide CCK-8 retains full activity
Little gastrin	2098	17	Both forms of gastrin are found in the gastric antrum and duodenum	Gastrins stimulate the secretion of gastric acid, pepsinogen, intrinsic factor, and secretin; stimulate intestinal mucosal growth; increase gastric and intestinal motility
Big gastrin	3839	34		
Secretin-Glucagon Family				
Secretin	3056	27	Duodenum and jejunum	Stimulates pancreatic secretion of HCO_3, enzymes, and insulin; reduces gastric and duodenal motility, inhibits gastrin release and gastric acid secretion
Vasoactive intestinal polypeptide (VIP)	3326	28	Enteric nerves	Relaxes smooth muscle of gut, blood, and genitourinary system; increases water and electrolyte secretion from pancreas and gut; releases hormones from pancreas, gut, and hypothalamus
Glucose-dependent insulinotropic peptide (GIP)	4976	42	Duodenum and jejunum	Stimulates insulin release; inhibits gastric acid, pepsin, and gastrin secretion; reduces gastric and intestinal motility; increases fluid and electrolyte secretion from small intestine

CCK regulates gallbladder contraction and increases small intestinal motility. It possesses the same terminal pentapeptide as gastrin, and therefore also has a mild stimulatory effect on gastric HCl and pepsinogen secretion, antral motility, and pancreatic bicarbonate secretion. Secretion of the less potent CCK results in a decreased output of HCl because CCK competes with gastrin for the receptor sites on the HCl-secreting cells. Conversely, gastrin and CCK are additive in their stimulation of the pancreas, and both increase the effect of secretin on pancreatic function. CCK also stimulates pancreatic growth, relaxes the sphincter of Oddi, and stimulates secretions from Brunner's (duodenal) glands.

CCK is also present in the brain, with highest concentrations in the cerebral cortex; its function in the CNS is unclear. It is released from the GI tract and acts as a short-term, meal-related satiety signal, thus regulating appetite. CCK is widely distributed throughout both the central and peripheral nervous systems.

Gastrin[130,148]

Three major molecular forms of gastrin occur in blood and tissues: big gastrin (G-34), a linear polypeptide of 34 amino acids; little gastrin (G-17); and mini gastrin (G-14). In addition to these, G-71, G-52, and G-6 are present in small amounts. Gastrins originate from the cleavage of a single precursor, preprogastrin, a peptide consisting of 101 amino acids. The smallest peptide sequence of gastrin possessing biological activity is the carboxy-terminal tetrapeptide (G-4, tetrin); on a molar basis, it is only one sixth to one tenth as

TABLE 48-11 Brief Description of Other GI Regulatory Peptides

Hormone/Peptide	Major Tissue Locations in Gut	Principal Known Actions
Bombesin	Throughout the gut and pancreas	Stimulates release of CCK and gastrin
Calcitonin gene-related peptide	Enteric nerves	Unclear
Chromogranin A	Neuroendocrine cells	Secretory protein
Enkephalins	Stomach, duodenum	Opiate-like actions
Enteroglucagon	Small intestine, pancreas	
Galanin	Enteric nerves	Inhibits insulin secretion
Ghrelin	Stomach	Appetite stimulation, increases gastric emptying
Glucagon-like peptide 1	Pancreas, ileum	Increases insulin secretion
Glucagon-like peptide 2	Ileum, colon	Enterocyte-specific growth hormone
Growth factors	Throughout the gut	Cell proliferation and differentiation
Growth hormone releasing factor	Small intestine	Unclear
Leptin	Stomach	Appetite control
Motilin	Throughout the gut	Increases gastric emptying and small bowel motility
Neuropeptide Y	Enteric nerves	Regulation of intestinal blood flow
Neurotensin	Ileum	Affects gut motility; increases jejunal and ileal fluid secretion
Pancreastatin	Pancreas	Inhibits pancreatic endocrine and exocrine secretion
Pancreatic polypeptide	Pancreas	Inhibits pancreatic and biliary secretion
PYY_{3-36}	Colon	Inhibits food intake
Somatostatin	Stomach, pancreas	Inhibits secretion and action of many hormones
Substance P	Enteric nerves	Unclear
Trefoil peptides	Stomach, intestine	Mucosal protection and repair

potent as G-17. A synthetic pentapeptide (pentagastrin) may be used for stimulation of HCl secretion in gastric function testing.

Gastrin is produced and stored mainly by endocrine cells (G cells) of the antral mucosa and to a lesser extent by G cells of the proximal duodenum and delta cells of the pancreatic islets. After secretion, gastrin is transported by the blood through the liver to the parietal cells of the fundus of the stomach, where it stimulates the secretion of gastric acid. Gastrin also stimulates secretion of gastric pepsinogens and intrinsic factor by the gastric mucosa, release of secretin by the small intestinal mucosa, and secretion of pancreatic bicarbonate and enzymes and hepatic bile; it also increases gastric and intestinal motility, mucosal growth, and blood flow to the stomach. It is secreted in response to antral distention meals, and by amino acids, peptides, and polypeptides from partially digested proteins in the stomach. Of the free amino acids, glycine, tryptophan, and phenylalanine are the most potent stimulators. Other stimuli of gastrin include alcohol, caffeine, insulin-induced hypoglycemia, ingestion or intravenous infusion of calcium, and vagal stimulation initiated by smelling, tasting, chewing, and swallowing food.

Maximal secretion of gastrin occurs at an antral pH of 5 to 7. At pH 2.5, secretion is reduced by about 80%; maximal suppression occurs at pH 1.0. Secretion is inhibited by the direct action of acid on the G cells. This negative feedback safeguards against over-acidification by any and all stimulants.

The principal circulating form of gastrin is G-34 in healthy individuals and in patients with hypergastrinemia. Trypsin cleaves G-34 into two fragments, one of which is identical to G-17. On a molar basis, G-17 is six to eight times more potent than G-34 as a stimulant for gastric acid secretion. In the fasting state, the ratio of G-34 to G-17 is about 2:1. After meals, the concentration of G-34 doubles, but that of G-17 increases four times so that the ratio of these two forms in the circulation becomes 1:1. The half-lives of endogenous human G-17 and G-34 in the circulation are about 6 and 36 minutes, respectively; this difference probably accounts for the higher concentration of G-34 in peripheral blood of individuals in the fasting state.

Secretin[130]

Secretin is a linear polypeptide containing 27 amino acids and has structural similarities to glucagon, VIP, GIP, peptide histadine-isoleucine (PHI), and growth hormone-releasing hormone. The amino acid residues at 14 positions within the molecule are identical with those found in glucagon; 8 are

the same as in GIP, and 9 are the same as in VIP. The intact secretin molecule is required for biological activity, and in contrast to gastrin there is no minimum active fragment.

Secretin is secreted by the mucosal granular S cells located in greatest concentration in the duodenum but present throughout the small intestine. It is released primarily on contact of the S cells with gastric HCl; however, as pancreatic juice flows into the duodenum, it neutralizes gastric acid and thereby removes one stimulus for its own secretion. Secretin is not released until the pH is lowered to at least 4.5. Below this pH, secretin release is proportional to the amount of acid entering the duodenum. A pH of <4.5 normally occurs only in the first few centimeters of the duodenum, causing little increase in plasma secretin after a normal meal. Thus secretin release after exposure of S cells to HCl may not be an important physiological stimulus. However, plasma secretin concentrations that are too low to measure may stimulate the pancreas in the presence of physiological concentrations of CCK, which is known to strongly potentiate the action of secretin. Undigested fat does not stimulate secretin release, but fatty acids with chains of 10 or more carbons are weak stimulants. Alcohol increases secretin release by stimulation of gastric acid secretion with subsequent lowering of duodenal pH rather than by a direct stimulatory effect. The half-life of secretin is about 4 minutes. The kidney is the major site of its degradation. The only known physiological inhibitor of secretin release is somatostatin.

The primary physiological role of secretin is the stimulation of the pancreas to secrete an increased volume of juice with high bicarbonate content. Other actions include stimulation of bicarbonate and water secretion from the liver and from Brunner's glands; augmentation of gallbladder contraction and increased hepatic bile flow; weak stimulation of insulin secretion (a pharmacological effect); stimulation of PTH release of pancreatic enzymes and of pepsinogen by the chief cells of the stomach; reduction of gastric and duodenal motility; reduction of the lower esophageal sphincter pressure; and promotion of pancreatic growth. Secretin inhibits normal gastrin secretion (but does not decrease serum gastrin in the Zollinger-Ellison syndrome) and therefore gastric acid secretion.

Vasoactive Intestinal Polypeptide[130]

VIP is a linear polypeptide consisting of 28 amino acids; it has structural similarities to secretin, GIP, and glucagon. VIP is present throughout the body and is found in highest concentrations in the nervous system and gut. Unlike secretin and other GI hormones, VIP is not found in the mucosal endocrine cells of the GI tract. VIP is believed to be a neurotransmitter limited to peripheral and central nervous tissue. VIP-containing nerve fibers are found throughout the GI tract from the esophagus to the colon and in all tissue layers of the gut.

Little is known about the conditions that cause VIP to be released into the circulation. There is no evidence that VIP is released during digestion, but its secretion is increased by vagal stimulation. It has a plasma half-life of about 1 minute, and most of the hormone is inactivated by a single passage through the liver.

VIP has a large number of ill-defined physiological actions, some of which are shared with other similar polypeptide hormones (secretin and GIP). It acts as a neurotransmitter in the central and autonomic nervous systems and causes vasodilation and relaxation of the smooth muscles of the circulatory and genitourinary systems and the gut. Other actions of VIP include an increase of water and electrolyte secretion from the pancreas and gut; release of hormones from the pancreas, gut, and hypothalamus; stimulation of lipolysis, glycolysis, and bile flow; and inhibition of gastrin and gastric acid secretion. Most of the actions of VIP tend to be of short duration because of its rapid degradation.

Glucose-Dependent Insulinotropic Peptide (GIP, Gastric Inhibitory Polypeptide)[130]

GIP is a linear peptide consisting of 42 amino acids. Its N-terminal end has a close resemblance to glucagon and secretin, but the C-terminal amino acid sequence of 17 residues is not common to any other known intestinal hormone.

GIP is synthesized and released by K cells located in the duodenal and jejunal mucosa. Plasma GIP is increased by oral administration of glucose, triacylglycerols, or intraduodenal infusions of solutions containing a mixture of amino acids; none of these, however, increases GIP concentrations when given intravenously. Protein ingestion does not significantly increase GIP. For food components to stimulate GIP release, they must be absorbed by the intestinal mucosa.

The biological actions of GIP include (1) stimulation of insulin secretion in the presence of hyperglycemia, (2) reduction of intestinal motility with stimulation of small intestinal fluid and electrolyte secretion, and (3) in supraphysiological concentrations, inhibition of gastric acid, pepsin, and gastrin secretion. The insulinotropic action of GIP appears to be the most important of its biological actions, and as a result, this hormone has more recently been called "glucose-dependent insulinotropic peptide" as a more accurate description of its physiological action.

Other Regulatory Peptides

Table 48-11 provides a brief description of the tissue locations and actions of other gut regulatory peptides, although the function of some of these is unclear. The growth factors belong to several families of peptides and have important roles in the control of a wide range of cell functions in the intestine.[38] The current clinical use of GI hormones/regulatory peptide measurements is in the diagnosis of neuroendocrine tumors of the pancreas and GI tract. It is likely that they will have wider applications as understanding of their functions grows (e.g., in the fields of obesity and appetite modulation).[30,31,136]

NEUROENDOCRINE TUMORS

GASTRINOMA AND THE ZOLLINGER-ELLISON SYNDROME[6,35,93]

In 1955, Zollinger and Ellison described a syndrome (Zollinger-Ellison or Z-E syndrome) consisting of fulminant peptic ulcers, massive gastric hypersecretion, and non-β-islet cell tumors of the pancreas. Hypergastrinemia, diarrhea, steatorrhea, and other endocrinopathies are frequent characteristics of this syndrome. Most cases occur between the ages of 30 and 50 years, although it has been described in patients from 7 to 90 years. It is more common in men (60% of cases) than in women. In about 25% of cases, ulcers are found beyond the first portion of the duodenum; such ulcers should always raise suspicion of Z-E syndrome. About 25% of all gastrinomas are part of the Multiple Endocrine neoplasia 1 syndrome (MEN1), which is characterized by tumors or hyperplasia in pancreatic islets and the parathyroid and pituitary glands. Fasting plasma gastrin is usually greatly increased, ranging from 2 to 2000 times normal. Concentrations more than 10 times the upper limit of normal, in the presence of gastric acid hypersecretion, are virtually diagnostic of gastrinoma. There is no correlation between the severity of the symptoms and the degree of elevation of the circulating gastrin concentration. However, the fasting plasma gastrin concentration at presentation in sporadic Z-E syndrome is associated with the size and site of the tumor and the presence of hepatic metastases and therefore has prognostic value.[9] Because management of the patient with Z-E syndrome usually requires surgical intervention, it is important to distinguish hypergastrinemia caused by gastrinoma from other conditions that may lead to similar increases in plasma gastrin.

Increased plasma gastrin occurs in hypochlorhydria or achlorhydria as a consequence of atrophic gastritis or the use of acid-suppressing drugs (e.g., histamine H_2-receptor antagonists or proton-pump inhibitors). Z-E syndrome cannot be diagnosed (or excluded) in patients taking PPIs. These drugs cause a profound reduction in gastric acid secretion and hence a large increase in plasma gastrin. *H. pylori* infection can also lead to increased plasma gastrin and to increased basal acid output, and in some cases to atrophic gastritis and high plasma gastrin.[89] Pernicious anemia and chronic atrophic gastritis associated with parietal cell antibodies are commonly associated with gastrin concentrations that overlap with those found in Z-E syndrome. Increases of plasma gastrin in chronic renal failure appear to be related to the severity of the renal failure. A direct correlation has been found between G-cell density and parathyroid function in patients with chronic renal failure, suggesting that secondary hyperparathyroidism may play a role in increasing plasma gastrin. Surgical resection or diseases of the kidneys or small intestine can cause hypergastrinemia, possibly because these are important sites of gastrin degradation or excretion.

Increased basal gastrin concentrations may be classified as "appropriate" or "inappropriate" according to their association with decreased or increased gastric acid secretion. In patients with very low or absent acid secretion and a functionally intact gastric antrum, an increase in plasma gastrin is physiologically appropriate and is expected. The increase is caused by hyperplasia of antral G cells as observed in atrophic gastritis, pernicious anemia, previous vagotomy, and renal failure. Inappropriate hypergastrinemia may be caused by gastrinoma, isolated retained antrum after gastric surgery, or primary G-cell hyperfunction.

Secretin and calcium provocation tests have been used in the past to assist in the differential diagnosis of Z-E syndrome.[64] The secretin test proved the more useful but is little used now with improved computed tomography scanning and the use of somatostatin-receptor imaging using the somatostatin analog octreotide.[109]

Measurement of Plasma Gastrin

In serum from healthy subjects, the predominant forms of gastrin are amidated G-34 and G-17. In subjects with gastrinomas, the circulating gastrins display unpredictable heterogeneity with a shift toward larger peptides. For the detection of gastrinomas, the assay should therefore be able to detect all secreted forms of gastrin to prevent false negatives.[66]

Gastrin is unstable in serum or plasma, and samples may lose up to 50% of their immunoreactivity during 48 hours at 2 °C to 8 °C, largely because of the action of proteolytic enzymes. Blood samples should be collected into a tube containing heparin as anticoagulant and aprotinin (e.g., Trasylol, 0.2 mL, 2000 KIU, in a 10 mL tube) to prevent proteolytic degradation. Samples should be mixed by inversion, transported rapidly on ice to the laboratory, and the plasma separated in a refrigerated centrifuge. The plasma should be frozen at −20 °C within 15 minutes of venipuncture. Samples collected in this way are suitable for the analysis of gastrin, VIP, pancreatic polypeptide, somatostatin, neurotensin, and chromogranins A and B.

THE WATERY DIARRHEA HYPOKALEMIA ACHLORHYDRIA SYNDROME (WERNER-MORRISON SYNDROME, WDHA SYNDROME, VIPOMA)[94]

The WDHA syndrome may be suspected in a patient producing large volumes (>1 liter/24 hours) of secretory diarrhea, with dehydration and hypokalemia. The diagnosis is confirmed by finding a high plasma VIP concentration and demonstration of the tumor by somatostatin-receptor imaging.

OTHER GASTROINTESTINAL NEUROENDOCRINE TUMORS AND TUMOR MARKERS

GI neuroendocrine tumors are either endocrine pancreatic tumors or carcinoid tumors arising from enterochromaffin cells, which occur throughout the GI tract. Carcinoid tumors are discussed in Chapter 29.

Approximately two thirds of patients with tumors arising from pancreatic islet cells present with clinical syndromes associated with the excessive hormone production.[109] This group of tumors includes insulomas, gastrinomas, VIPomas, glucagonomas, and somatostatinomas. Insulinomas and glucagonomas are not usually associated with GI symptoms. Gastrinomas and VIPomas have been discussed in preceding sections. The somatostatinoma syndrome is associated with steatorrhea, gallstones, and diabetes. The remaining one third of patients with endocrine pancreatic tumors have no specific clinical symptoms associated with the tumors, which are described as nonfunctional.

The pattern of hormone and precursor production by neuroendocrine tumors is complex. Most secrete several tumor markers. Chromogranin A, a member of a family of secretory proteins, has the highest diagnostic sensitivity (94%) for endocrine pancreatic tumors, followed by pancreatic polypeptide (74%).[50] Chromogranin A is elevated in most patients and is an alternative to more specific markers in monitoring the effectiveness of surgery or drug therapy. However, as with other protein and peptide tumor markers, the epitope specificity of the antiserum has a profound effect on the diagnostic sensitivity of the assay.[109] Although chromogranin A has high sensitivity, false positives have been observed in a number of nonendocrine tumors including prostatic cancer.

INVESTIGATION OF MALDIGESTION/MALABSORPTION

This section summarizes causes of malabsorption and suggests the general laboratory approach to these disorders.

Box 48-8 summarizes the main causes of malabsorption under the three categories of (1) intraluminal disorders and malabsorption due to disorders of (2) transport into the mucosal cells, and (3) transport out of the mucosal cells.

Clinical presentation of the patient suffering from malabsorption or maldigestion classically includes the following features:

- *Evidence of general ill health.* Anorexia, weight loss, fatigue following minor effort, and dyspnea may be seen. Edema (due to hypoalbuminemia or weakness), tetany, and dehydration due to electrolyte imbalance and water loss may be present. In pancreatic exocrine insufficiency, however, hyperphagia is the rule; patients often report a very high (5000 kcal/day) food intake.
- *Isolated nutritional deficiencies.* Iron, folate, or vitamin B_{12} deficiency may manifest as anemia, which may be mild; vitamin K deficiency as a bleeding tendency; and vitamin D deficiency as bone disease. They are reflected by a variety of signs and symptoms (glossitis, pallor, dermatitis, petechiae, bruising, hematuria, muscle or bone pain, or neurological abnormalities).
- *Abdominal symptoms*, such as discomfort, distention, flatulence, and borborygmi (rumbling and gurgling sounds due to movement of gas in the intestine).
- *Watery diarrhea and possibly steatorrhea.* In severe cases of steatorrhea (excess fat in feces), the stool is typically loose, bulky, offensive, greasy, light-colored, and difficult to flush away. Alternatively the stools may appear normal, but be more bulky or be passed with greater frequency.

Early presentation of malabsorption will, however, be more subtle than this list would indicate. There may be only a slight alteration in volume or consistency of the stool and only mild symptoms attributable to the GI tract. The patient may complain only of anorexia, fatigue, and lack of interest in daily activities. It is in these cases that the physician who suspects malabsorption on clinical grounds will rely on the laboratory to assist in the diagnosis. The initial laboratory investigations are routine tests, abnormalities of which may point to the possibility of malabsorption (e.g., blood hemoglobin concentration; mean red cell volume; serum concentrations of folate, ferritin, calcium, albumin, and alkaline phosphatase; and tests for antibodies in celiac disease [celiac serology]).

EVALUATION OF FAT ABSORPTION (FROM HILL,[79] WITH PERMISSION)

The evaluation of fat absorption or malabsorption is required in a small minority of patients being investigated for GI disorders. The British Society of Gastroenterology (BSG) guidelines[168] state that gastroenterologists should have access to such tests to "... assess patients with malabsorption who are proving difficult to diagnose."

BOX 48-8 Summary of Disorders Leading to Malabsorption

Disorders of intraluminal digestion:		
a.	Altered gastric function	Post gastrectomy syndrome Zollinger-Ellison syndrome
b.	Pancreatic insufficiency	Chronic pancreatitis Cystic fibrosis Pancreatic cancer
c.	Bile acid deficiency	Disease/resection of terminal ileum Small bowel bacterial overgrowth
Disorders of transport into the mucosal cell:		
a.	Generalized disorders due to reduction in absorptive surface area	Celiac disease, tropical sprue
b.	Specific disorders	Hypolactasia Vitamin B_{12} in pernicious anemia Zn in acrodermatitis enteropathica
Disorders of transport out of the mucosal cell:		
a.	Blockage of the lymphatics	Abdominal lymphoma Primary lymphangiectasia
b.	Inherited disorders	a-β-lipoproteinemia

In a survey in 1997 of 231 hospitals in the UK,[45] fecal fat was the most widely available of all tests, with the estimated number of fecal fat measurements performed annually in the UK being 6100. Fecal fat measurement has many limitations,[86] some of which were highlighted in the 1997 survey, which must be brought to the attention of clinicians to dissuade them from placing reliance on an inherently unreliable test. In addition, dialogue with local gastroenterologists is necessary to reach consensus that the quantitative demonstration of fat malabsorption is of little value for most patients.

Limitations of Fecal Fat Measurement

The case for abandoning fecal fat measurement can be made on the grounds both of physiology and of analytical performance. The physiological problems of sample collection were convincingly demonstrated in a study in which radio-opaque pellets were administered orally (8, three times a day) for 5 days (120 total), and feces were collected for days 3 to 5.[182] Radiographic detection of 72 pellets was taken to indicate 100% recovery. In 52 patients studied, recovery ranged from 14% to 125%, and recovery was within the range 85% to 115% in only 32 of them. In 7 patients, fecal fat was normal but became abnormal after adjustment for marker recovery. Despite this evidence, few laboratories attempt to assess completeness of collection using markers.

Absorption of dietary fat is a remarkably efficient process, so that in normal health, fecal fat is largely (if not entirely) derived from endogenous rather than dietary sources.[41,77,103] Adequate dietary fat intake is therefore essential to minimize false-negative results. The BSG guidelines recommend a diet containing at least 70 g fat for 6 days.[168] In the UK only a minority of laboratories try to control (20%) or retrospectively assess (8%) fat intake.[45] Patients with steatorrhea may reduce their fat intake to control their diarrhea and despite laboratory instructions may not increase their dietary fat before and during the 72 hours of fecal collection; this will result in misleadingly low results.[41]

It is also often forgotten that diarrhea increases fecal fat excretion. In 58% of subjects with normal fat excretion, experimental induction of severe diarrhea (fecal weight >800 g/day) led to increased fecal fat (values of up to 49 mmol/day).[57] A borderline increase in fecal fat (i.e., 2 to 3 times the upper limit of normal, which is 18 mmol/day) is therefore not specific for a primary defect in fat digestion or absorption.

Available analytical performance data for fecal fat measurements in the UK also indicate that the test should now be consigned to history. Eighty-two per cent of laboratories use no internal quality control and EQA is impractical. When the titration step was assessed in an EQA exercise, between-laboratory coefficients of variation for three samples ranged from 31% to 42%.[45] Infrared spectroscopy offers the possibility of improved within- and between-laboratory precision for fecal fat measurements,[91] but does not address the problems of dietary input and sample collection, and is unlikely to be available to most laboratories.

At the end of an extensive survey of hospital laboratories in the UK, Duncan (unpublished report of the Clinical Resource and Audit Group, Scottish Office, Edinburgh 1997) concluded that ". . . the current utilization of the test, with no control of dietary fat intake, no correction for incomplete fecal collections and misgivings over analytical reliability, makes it a highly unsatisfactory investigation and probably of little clinical value."

Quantitative Demonstration of Fat Malabsorption Is Rarely Necessary

Many requests for fecal fat can be avoided or rejected by asking the requesting physician how the demonstration of fat malabsorption will help in the diagnosis of the disorder or management of the patient (see Table 48-12). In most cases it will become evident that neither fecal fat nor an alter-

TABLE 48-12 Common Situations in Which Fecal Fat May Be Requested But Is Unhelpful in Diagnosis and Management

Clinical Picture or Question	Appropriate Laboratory Response
Abdominal pain, weight loss, and diarrhea; possibly small bowel problem	Celiac serology: consider small bowel radiology
Offensive, floating, light colored stools	None (demonstrating fat malabsorption will not provide a diagnosis)
Elderly patient, weight loss, possibly malabsorption	Fat intake probably too low for fecal fat measurement; encourage use of appropriate investigations (see Table 48-13)
Pancreatic insufficiency, patient on enzyme supplements	Monitor stool consistency and clinical response (weight gain); may occasionally need to assess fat absorption
Abdominal pain, weight loss, and possibly pancreatic insufficiency	Use a specific pancreatic function test
Child, foul stool, possibly malabsorption	May sometimes need to confirm presence of fat globules in stool

From Hill PG, Ann Clin Biochem 2001;38:164-7.

TABLE 48-13 Laboratory Tests to Assess GI Function

Clinical Application	Appropriate Laboratory Investigations
Investigating diarrhea	Possible lactase deficiency: breath hydrogen after oral lactose
	Possible bacterial overgrowth: breath hydrogen after oral glucose or lactulose
	Possible laxative abuse: urine laxative screen
	Possibly induced by bile acid: ^{75}selenohomocholyltaurine whole body retention or serum 7α-hydroxy-4-cholesten-3-one
	Fecal osmotic gap; fecal Na, K
Assessing pancreatic function	Pancreolauryl test, fecal elastase
Screening for celiac disease	Tissue transglutaminase antibodies
Assessing fat absorption	^{14}C-triolein absorption (breath $^{14}CO_2$) or fecal microscopy
Other tests	Fecal α-1-antitrypsin for protein-losing enteropathy; gut hormones (gastrin)

From Hill PG, Ann Clin Biochem 2001;38:164-7.

BOX 48-9 Tests for Assessing Fat Absorption and Malabsorption

Measurement of fecal fat
Problems of poor recovery during sample collection (requires use of markers), inadequate dietary fat (minimum of 70 g/day), inaccurate analysis and uncertain interpretation

Butter fat test
Unreliable, poor discrimination

^{14}C-glyceryl trioleate
Sensitivity 85%, specificity 93%
Important factors to consider
Fat load (20 g) and form of "meal"
Effect of fat load on timing of peak of breath CO_2
Effect of assuming a constant CO_2 output of 9 mmol/kg/hr
Inappropriate in:
Liver, thyroid, and severe respiratory disease, diabetes, obesity, pregnancy

Mixed-chain triglyceride breath test
Valid test for pancreatic steatorrhea

Fat globules (fecal microscopy)
Need for standardized procedure

native test for assessing fat absorption is necessary. There is no justification for assessing fat absorption for the diagnosis or management of celiac disease, and a specific pancreatic function test is more appropriate for the investigation of suspected pancreatic disease. Measuring fecal fat in patients with offensive, floating, putty-colored stools will not provide a diagnosis.

It is essential to encourage clinicians to use appropriate newer tests of GI function directed toward specific clinical situations (see Table 48-13). The availability and use of these tests will discourage the inappropriate use of fecal fat measurement.

There still remains the question, "Which test should be used when the assessment of fat malabsorption really is indicated?" Box 48-9 indicates the range of possible tests. My district hospital laboratory, serving a population of about 500,000, offers fecal microscopy and the ^{14}C-glycerol trioleate (^{14}C-triolein) fat absorption test.[176]

In the 1997 survey, performance of fecal microscopy was very poor (sensitivity 26%, specificity 64%); however, several studies have reported high sensitivity and specificity figures when compared with those derived from fecal fat measurement.[116,121] Some have argued that fecal microscopy after staining with Sudan III has advantages over fecal fat measurement, because it detects fecal triglycerides and fatty acids, which are principally of dietary origin; fecal fats include phospholipids and cholesteryl esters, which largely originate from the turnover of intestinal epithelial cells and gut bacteria.[102] There is still a need to evaluate a well-defined standardized technique for fat globules by fecal microscopy in a multilaboratory study. Meanwhile, Duncan has made several recommendations (unpublished report as above) to improve current performance related to methodology, interpretation, quality control, and adequate dietary fat before collecting fecal samples.

The ^{14}C-triolein test has been in use in my department since about 1985. The current workload is 10 to 15 patients per year from four gastroenterologists serving a population of about 500,000. In a prospective evaluation in 57 patients, the reported sensitivity was 85%, with specificity of 93% for the detection of fat malabsorption.[176] The "gold standard" for fat malabsorption was the final diagnosis made on clinical, histological, and radiological or laboratory grounds. Currently in the UK, various fat loads and procedures are used.[45] It is clear that larger fat loads (e.g., 60 g) result in significant delays in peak $^{14}CO_2$ in exhaled breath.[43] Our procedure uses a fat load of 19.3 g prepared as a palatable lemon mousse, containing protein (1.4 g) and carbohydrate (10 g). Peak $^{14}CO_2$ occurred within 6 hours in all subjects studied who had normal fat absorption. However, it must be recognized that the standard assumed CO_2 output of 9 mmol/kg/hr may lead to significant errors in the $^{14}CO_2$-triolein test because actual output varies from 5 to 12.4 mmol/kg/hr.[43]

When a similar fat load was used without the inclusion of protein and carbohydrates, peak $^{14}CO_2$ occurred later in some patients. In 53 patients in whom $^{14}CO_2$ excretion peaked within 6 hours, the sensitivity and specificity of the tests were 100% and 96%, respectively.[43] Breath samples for $^{14}CO_2$ measurement are not easily transportable, and the requirement for a scintillation counter and the administrative regulations surrounding the use of radioisotopes deter many laboratories from using the test.

With the growing interest in the application of stable isotopes, ^{13}C-substrates may replace the use of ^{14}C-triolein. A breath test using ^{13}C-mixed-chain triglycerides [1,3-distearyl, 2(carboxyl-^{13}C) octanoyl glycerol] has been used in children[2] and adults.[177] With a medium-chain fatty acid in the 2-position, the test is designed to assess intraluminal pancreatic lipase activity and is not therefore a substitute for fecal fat measurement. The ^{13}C-triolein test, using a uniformly labeled long chain triglyceride, is an alternative to fecal fat measurement.[112]

The van de Kamer method[96] for measuring fecal fat has survived for 5 decades. It really is time to give it up as a routine diagnostic test and to encourage the wider use of more specific tests for investigating disorders of GI function.

INVESTIGATION OF CHRONIC DIARRHEA

Although diarrhea is a common problem, no clear definition has existed to distinguish it from the range of stool weight, frequency, consistency, or volume that occurs in the normal population. A recent proposal, which seeks to encompass these different elements, suggests that for a Western diet, diarrhea may be defined as "the abnormal passage of loose or liquid stools more than three times daily and/or a volume of stool [with a weight] greater than 200 g/day."[171] Guidelines suggest that diarrhea may be defined as chronic when it has continued for 4 weeks; such persistence indicates the likelihood of a noninfectious cause requiring further investigation.

Several quite different mechanisms can lead to diarrhea. In carbohydrate malabsorption, the presence of unabsorbed solutes in the bowel causes an osmotic diarrhea as water enters the bowel from the tissue. By contrast, the diarrhea of most laxative abuse and in VIPomas is due to active secretion of water and electrolytes into the bowel, which is described as secretory diarrhea. Inflammatory bowel diseases (ulcerative colitis and Crohn's disease) cause diarrhea as a consequence of the inflammatory process with loss of fluid into the bowel.

Many diseases commonly thought to cause "diarrhea" in fact lead to more frequent passage of stools but not usually to an increased stool weight (or volume). Such disorders (e.g., irritable bowel syndrome) generally fall outside the scope of the definition of "chronic diarrhea." Guidelines for the management of irritable bowel syndrome are available.[95]

BOX 48-10 Causes of Chronic Diarrhea

- Colonic:
  - Colonic neoplasia
  - Ulcerative and Crohn's colitis
  - Microscopic colitis
- Small bowel:
  - Celiac disease
  - Crohn's disease
  - Other small bowel enteropathies (e.g., Whipple's disease, tropical sprue, amyloid, intestinal lymphangiectasia)
  - Bile salt malabsorption
    - Disaccharidase deficiency
    - Small bowel bacterial overgrowth
    - Mesenteric ischemia
    - Radiation enteritis
    - Lymphoma
    - Giardiasis (and other chronic infection)
- Pancreatic:
  - Chronic pancreatitis
  - Pancreatic carcinoma
  - Cystic fibrosis
- Endocrine:
  - Hyperthyroidism
  - Diabetes
  - Hypoparathyroidism
  - Addison's disease
  - Hormone secreting tumors (VIPoma, gastrinoma, carcinoid)
- Other:
  - Factitious diarrhea
  - "Surgical" causes (e.g., small bowel resection, internal fistulae)
  - Drugs
  - Alcohol
  - Autonomic neuropathy

Box 48-10 describes the many causes of chronic diarrhea; most chronic diarrhea is due to disease of the colon in which laboratory diagnostic tests are currently of little value. A helpful algorithm for the investigation of chronic diarrhea is given in Figure 48-11.

The investigation of laxative abuse and measurement of fecal osmotic gap are described below. The other laboratory tests required for the investigation of chronic diarrhea are described in the sections above on intestinal disease, pancreatic diseases, and neuroendocrine tumors.

LAXATIVE ABUSE[42]

Surreptitious laxative abuse is an important cause of chronic diarrhea, is often overlooked, and is a diagnosis in which laboratory investigations have a significant role. It is the final diagnosis for chronic diarrhea in 15% to 26% of patients investigated in secondary or tertiary referral centers[18,46,144,146]

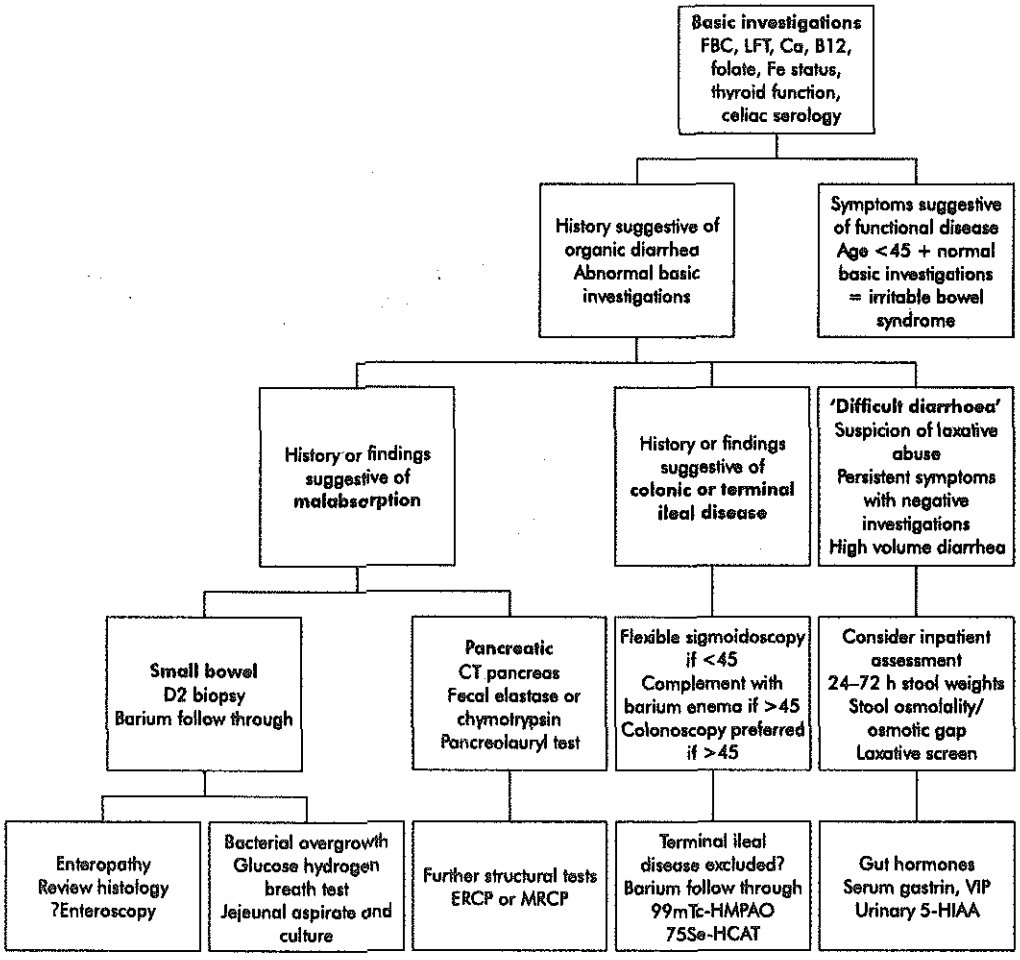

Figure 48-11 An algorithm for the investigation of chronic diarrhea. *FBC,* Full blood count; *LFT,* liver function tests; *CT,* computed tomography; *ERCP,* endoscopic retrograde cholangiopancreatography; *MRCP,* magnetic resonance cholangiopancreatography; *Tc-HMPAO,* technetium hexa-methyl-propyleneamine oxime; *75Se-HCAT,* 75Se homotaurocholate; *5-HIAA,* 5-hydroxyindoleacetic acid. *(From Thomas PD, Forbes A, Green J, Howdle P, Long R, Playford R, et al. Guidelines for the investigation of chronic diarrhoea, 2nd edition. Gut 2003;52(Suppl V):v1-v15. Used with permission of the BMJ Publishing Group.)*

and in 4% of a consecutive series of new primary care referrals to a gastroenterology clinic for evaluation of diarrhea.[46] The financial benefits of screening for laxative abuse have been established: When the diagnosis is not considered early in the investigative pathway, extensive and unnecessary investigations may occur.[18] In Munchausen syndrome by proxy, adults have administered laxatives surreptitiously to young children. A clinical diagnosis can rarely be made; no single clinical feature reliably predicts a positive test, making laboratory support essential. The main initial prerequisite for making a diagnosis of surreptitious laxative abuse is a high index of clinical suspicion,[42] followed by a request for appropriate analyses in urine and fecal samples at a time when the patient has diarrhea.

The pattern of laxative abuse has changed following legislation in several countries banning over-the-counter sales of laxatives containing phenolphthalein, which has traditionally been the most widely abused laxative. Abuse of phenolphthalein will therefore become less common, and the laxatives that will most frequently be encountered by clinical laboratories will be colonic stimulants containing bisacodyl or anthroquinones (e.g., senna, aloin, and cascara). Their absorption, metabolism, and excretion have recently been reviewed.[42] These can be detected in urine for at least 32 hours after a single dose.[184] Magnesium salts are the active ingredient of some over-the-counter laxatives and these may also be abused. The only reliable diagnostic procedure is the measurement of magnesium in fecal water. Concentrations >30 mmol/L are suggestive of magnesium-induced diarrhea.[44]

A pilot National External Quality Assurance Scheme was set up in the United Kingdom in 1996. In the light of poor overall performance highlighted by the scheme, recommendations have been made for a laxative screening service.[42]

Subsequently, thin layer chromatography (TLC) methods have been extensively evaluated to optimize the detection of laxatives.[47] The most important findings for the successful detection of laxatives by TLC were (1) the skill and experience of the operator, (2) the choice of the mobile phase (ethyl acetate:toluene:glacial acetic acid [4:16:1] and hexane:toluene:glacial acetic acid [3:1:1] gave the best results), and (3) use of high-performance TLC plates with a concentrating zone.

As for other laboratory procedures, a reliable laboratory service is essential. For such tests, false positives or false negatives may have important implications both for the patient's management and for the clinician's confidence in the laboratory. The analysis of laxatives should be regarded as part of the toxicology service, with confidence in the initial screening by TLC and ideally confirmation of positive results by mass spectrometry. Analyses should be undertaken by laboratories with appropriate expertise and ability to demonstrate good performance for these tests so as to ensure that patients with chronic diarrhea are correctly diagnosed and managed.

Fecal Osmotic (Osmolal) Gap

The osmolality of stool "water" will normally be that of serum (i.e., 290 mosm/kg), but the contribution of electrolytes and of nonelectrolytes to the total osmolality will vary depending on the cause of the diarrhea. Fecal osmotic (osmolal) gap (FOG) expresses the difference between the theoretical normal osmolality (290 mosm/kg) and the contribution of Na^+ and K^+ as follows:

$$\text{Fecal osmotic gap} = 290 - [2(\text{fecal } Na^+ + K^+)]$$

Fecal sodium and potassium can be measured in the fluid obtained by rapid centrifugation of a fecal sample. Total fecal osmolality increases significantly in unrefrigerated samples and use of the serum osmolality or 290 mosm/kg has been recommended in the above formula rather than a measurement of total fecal osmolality.[48]

Measurement of FOG enables an estimate to be made of the contribution of electrolytes or nonelectrolytes to the retention of water in the bowel and can therefore assist in distinguishing between secretory and osmotic diarrhea. In osmotic diarrhea, unabsorbed solutes lead to water retention and will thus make a larger contribution than normal to fecal osmolality; fecal sodium and potassium will therefore be present at lower concentrations than normal, leading to a larger "osmotic gap." Conversely, in secretory diarrhea, it is electrolytes that lead to water retention, and the FOG will therefore be small. FOG >50 mosm/kg is consistent with an osmotic diarrhea from carbohydrate malabsorption or magnesium-induced diarrhea[44]; by contrast FOG <50 mosm/kg suggests a secretory diarrhea, and further investigations might include a laxative screen for colonic stimulants or rarely tests for a neuroendocrine tumor.[58] A low FOG will be found in factitious diarrhea because of the addition of water to the stool; if this is suspected and if other causes are excluded, then measurement of total stool osmolality may be helpful.[99]

Measurement of creatinine can be used as an indication of contamination of the fecal sample with urine.

CHAPTER 49

Mineral and Bone Metabolism

David B. Endres, Ph.D., and Robert K. Rude, M.D.

Among the multitude of homeostatic processes in the body, one of the most tightly controlled is the metabolism of calcium. This tight control is necessary because calcium has critical roles in intracellular signaling, at the plasma membrane of cells, and in control of function of extracellular proteins, such as those in the coagulation cascade. The body's handling of extracellular calcium is closely intertwined with that of phosphate and to a somewhat lesser extent of magnesium. It is also intricately connected with the active cellular processes in bone, which is the body's storehouse of calcium and a metabolically and functionally important system in its own right.

In this chapter, after an overview of bone and mineral metabolism, we discuss the clinical chemistry of calcium, phosphate, and magnesium; the hormones regulating these minerals; the major disorders of bone; and the clinical use of markers of bone formation and degradation. A goal of the chapter is to provide, in one place, a view of these highly interrelated topics.

OVERVIEW OF BONE AND MINERAL

The main functions of bone are (1) mechanical, for locomotion; (2) protective, for organs; and (3) metabolic, as a reserve for minerals, especially calcium and phosphate. Bones are composed of cortical and trabecular bone. Cortical (compact) bone is 80% to 90% mineralized by volume and constitutes 80% of the skeleton. Its function is primarily mechanical and protective. Trabecular bone constitutes the remaining 20% of the skeleton. Trabecular (cancellous or spongy) bone, which is 15% to 25% mineralized, is more metabolically active.

Bone is composed primarily of an extracellular mineralized matrix with a smaller cellular fraction. The organic matrix is primarily type I collagen (90%) with lesser amounts of a large number of noncollagenous proteins including osteocalcin. The organic matrix is mineralized by the deposition of inorganic calcium and phosphate in small, imperfect hydroxyapatite crystals with lesser amounts of carbonate, magnesium, sodium, potassium, and various ions. *Osteoclasts* and *osteoblasts*, the two main types of bone cells, are located on surfaces undergoing bone resorption and formation, respectively. Osteoclasts resorb bone, whereas osteoblasts participate in the synthesis of new bone.

Continuous turnover or *remodeling* of bone occurs, enabling bone to repair damage and adjust strength. Bone remodeling does not occur at random, but instead in discrete packets known as *bone remodeling units*. Bone resorption and bone formation are coupled. The remodeling cycle can be divided into activation, resorption, reversal, formation, and resting phases (Figure 49-1). Circulating osteoclast precursors are recruited, proliferate, and fuse to form osteoclasts. These giant multinucleated cells resorb bone by producing hydrogen ions to mobilize minerals and lysosomal enzymes to digest the organic matrix. Deep foldings of their plasma membrane (ruffled border) are in contact with the bone surface, forming the osteoclastic bone-resorbing compartment. After resorption ceases, a cement line is deposited in the resorption cavity, probably by mononucleated cells. Stromal lining cells differentiate to osteoblasts. Osteoblasts form bone by synthesizing the organic matrix, including type I collagen, and participating in the mineralization of the newly synthesized matrix. Remodeling is followed by a quiescent phase. An estimated 10% to 30% of the skeleton is remodeled each year.

Bone growth and turnover are influenced by the metabolism of calcium, phosphate, and magnesium and a number of hormones, the primary ones being parathyroid hormone (PTH) and 1,25-dihyroxyvitamin D (1,25$[OH]_2$D). In addition, a large number of other hormones and factors are

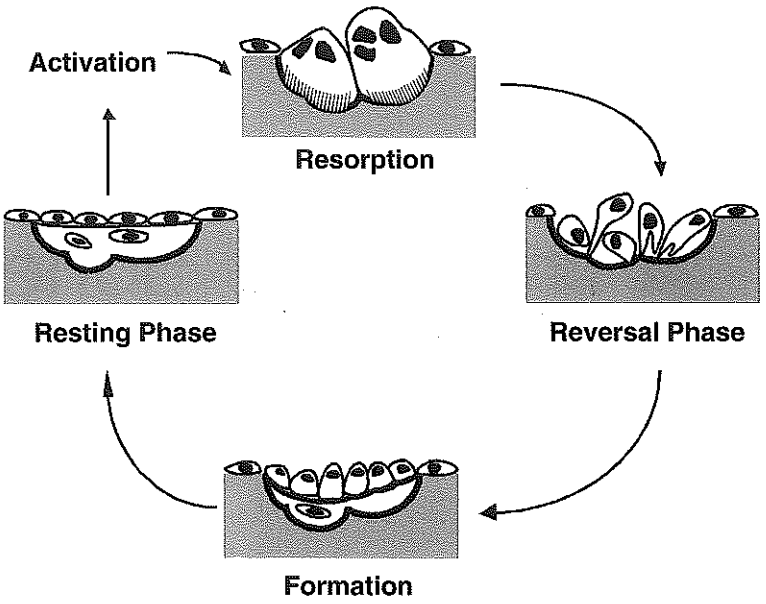

Figure 49-1 Bone remodeling. The bone remodeling sequence includes activation, reversal, formation, and resting phases. Reproduced from Baron R 2003 General Principles of Bone Biology. In: Favus M (ed.) *The Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism*, 5th ed. American Society for Bone and Mineral Research, Washington DC, USA, pp. 1–8 with permission of the American Society for Bone and Mineral Research.

involved in the regulation of bone formation and resorption, including thyroid hormones, estrogens, androgens, cortisol, insulin, growth hormone, insulin-like growth factors (IGF-I and IGF-II), transforming growth factor β (TGF-β), fibroblast growth factor (FGF), and platelet-derived growth factor (PDGF). A number of cytokines, including interleukin (IL)-1, -4, -6 and -11; macrophage and granulocyte/macrophage colony-stimulating factors; and tumor necrosis factor (TNFα) alter bone remodeling primarily by stimulating resorption.

Recently, two products of the osteoblast have been identified that appear to be the final common pathway in coordinating osteoblast and osteoclast activity.[70,255] The first, receptor activator of nuclear factor-κB (RANK) ligand, binds to a receptor on osteoclast progenitor cells and increases osteoclast differentiation and activity. The second, osteoprotegerin (OPG), serves as a decoy receptor for RANK ligand. When OPG binds to RANK ligand, the osteoclast-stimulation activity is prevented. The relative ratios of these two molecules determine bone turnover.

Significant research progress has increased our understanding of bone and mineral metabolism and the pathophysiology of associated disorders. At the same time, improvements in technology have allowed laboratories to expand their role from measuring total calcium, phosphate, and magnesium to measuring other analytes, such as free (ionized) calcium, intact PTH, vitamin D metabolites, and calcitonin. An aging population is accelerating this trend and increasing the need for determining other analytes, such as biochemical markers of bone resorption (collagen cross-links [deoxypyridinoline and telopeptides]) and bone formation (osteocalcin and bone alkaline phosphatase [BAP]) and parathyroid hormone-related protein (PTHrP).

Bone contains nearly all of the calcium (99%), most of the phosphate (85%), and much of the magnesium (55%) of the body. The concentrations of calcium, phosphate, and magnesium in plasma are dependent on the net effect of bone mineral deposition and resorption, intestinal absorption, and renal excretion. PTH and 1,25-dihydroxyvitamin D are the principal hormones regulating these three processes.

CALCIUM

Calcium is the fifth most common element, and the most prevalent cation, in the body. An average human body contains approximately 1 kg (24.95 mol) of calcium. Calcium is found in three main compartments: the skeleton, soft tissues, and extracellular fluid (Table 49-1).[23,41] The skeleton contains 99% of the body's calcium, predominantly as extracellular crystals of unknown structure with a composition approaching that of hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$]. Soft tissues and extracellular fluid contain about 1% of the body's calcium.

Biochemistry and Physiology

In blood, virtually all of the calcium is in the plasma, which has a mean normal calcium concentration of approximately 9.5 mg/dL (2.38 mmol/L). Calcium exists in three physiochemical states in plasma (Table 49-2), of which approxi-

TABLE 49-1 Distribution of Calcium, Phosphate, and Magnesium in the Body

Tissue	Calcium	Phosphate	Magnesium
Skeleton	99%	85%	55%
Soft tissues	1%	15%	45%
Extracellular fluid	<0.2%	<0.1%	1%
Total	1000 g (25 mol)	600 g (19.4 mol)	25 g (1.0 mol)

Modified from Aurbach GD, Marx SJ, Speigel AM. Parathyroid hormone, calcitonin, and the calciferols. In: Wilson JD, Foster DW, eds. Williams textbook of endocrinology, 8th ed. Philadelphia: WB Saunders, 1992:1397-476.

TABLE 49-2 Physiochemical States of Calcium, Phosphate, and Magnesium in Normal Plasma

	Approximate Percent of Total		
State	Calcium	Phosphate	Magnesium
Free (ionized)	50	55	55
Protein-bound	40	10	30
Complexed	10	35	15
Total (mg/dL)	8.6-10.3	2.5-4.5	1.7-2.4
(mmol/L)	2.15-2.57	0.81-1.45	0.70-0.99

Modified from Marshall RW. Plasma fractions. In: Nordin BEC, ed. Calcium, phosphate and magnesium metabolism. London: Churchill Livingstone, 1976:162-85.

mately 50% is free (ionized), 40% is bound to plasma proteins, and 10% is complexed with small anions.

The free calcium fraction is the biologically active form. Its concentration in plasma is tightly regulated by the calcium-regulating hormones PTH and 1,25-dihydroxyvitamin D.

About 80% of protein-bound calcium is associated with albumin,[189,314] with the remaining 20% associated with globulins. Because calcium binds to negatively charged sites on proteins, its binding is pH dependent. Alkalosis leads to an increase in negative charge and binding and a decrease in free calcium; conversely, acidosis leads to a decrease in negative charge and binding and an increase in free calcium. In vitro, for each 0.1-unit change in pH, approximately 0.2 mg/dL (0.05 mmol/L) of inverse change occurs in the serum free calcium concentration. In some patients with multiple myeloma, the high concentrations of serum globulin may bind sufficient calcium to produce an increase in the total serum calcium concentration.

Complexed calcium, about 10%, is complexed with small diffusible inorganic and organic anions, including bicarbonate, lactate, phosphate, and citrate.

Calcium can be redistributed among the three plasma pools, acutely or chronically, by alterations in the concentration of protein and small anions, changes in pH, or changes in the quantities of free calcium and total calcium in the serum (Figure 49-2).

Physiologically, calcium is classified as either intracellular or extracellular. The skeleton is a major reservoir for providing calcium for both the extracellular and intracellular pools. Intracellular calcium has key roles in many important physiological functions, including muscle contraction, hormone secretion, glycogen metabolism, and cell division.[23,449] The intracellular concentration of calcium in the cytosol of unstimulated cells is $<10^{-6}$ to 10^{-7} mol/L or lower, which is less than 1/1000 of that in the extracellular fluid (10^{-3} mol/L).

Extracellular calcium provides calcium ion for the maintenance of intracellular calcium, bone mineralization, blood coagulation, and plasma membrane potential. Calcium stabilizes the plasma membranes and influences permeability and excitability. A decrease in the serum free calcium concentration causes increased neuromuscular excitability and tetany; an increased concentration reduces neuromuscular excitability.

Clinical Significance

Disorders of calcium metabolism are separated into those causing hypocalcemia and hypercalcemia.

Hypocalcemia

Low total serum calcium (hypocalcemia) may be due to either a reduction in the albumin-bound calcium, the free fraction of calcium, or both (Box 49-1).[23,41,485] Hypoalbuminemia is the most common cause of pseudohypocalcemia (decreased total and normal free calcium) because 1 g/dL of albumin binds approximately 0.8 mg/dL of calcium. Common clinical conditions associated with low serum

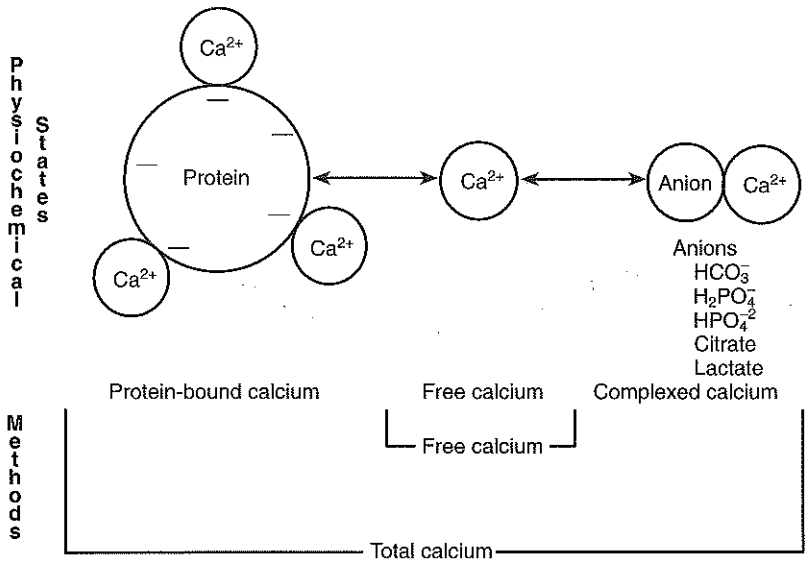

Figure 49-2 Equilibria and determinations of calcium in serum. Calcium can move among three physiochemical pools: (1) free calcium, (2) protein-bound calcium, and (3) calcium complexed with inorganic and organic anions. Methods for determining total calcium measure all three pools, whereas methods for determining free calcium measure only that pool.

BOX 49-1 Differential Diagnosis of Hypocalcemia

Hypoalbuminemia
Chronic renal failure
Magnesium deficiency
Hypoparathyroidism
Pseudohypoparathyroidism
Osteomalacia and rickets due to vitamin D deficiency or resistance
Acute hemorrhagic and edematous pancreatitis
Healing phase of bone disease of treated hyperparathyroidism, hyperthyroidism, and hematological malignancies (hungry bone syndrome)

albumin include chronic liver disease, nephrotic syndrome, congestive heart failure, and malnutrition.

Common causes of hypocalcemia are chronic renal failure and hypomagnesemia. In chronic renal failure, hypoproteinemia, hyperphosphatemia, low serum $1,25(OH)_2D$ (reduced synthesis because of inadequate renal mass), and/or skeletal resistance to PTH contribute to hypocalcemia. Magnesium deficiency, as discussed in a later section of this chapter, impairs PTH secretion and causes PTH end-organ resistance.

Other causes of low serum calcium are less common.[415] Hypoparathyroidism is due most commonly to parathyroid gland destruction during neck surgery (90%), and less commonly is idiopathic. Pseudohypoparathyroidism is biochemically similar to hypoparathyroidism; however, these patients have inherited resistance to PTH and elevated concentrations of PTH.[331] The molecular basis for the most common form, pseudohypoparathyroidism type I (Albright's hereditary osteodystrophy), is a reduction in guanine nucleotide regulatory complex, Ns, in the adenylate cyclase complex.

Acute symptomatic hypocalcemia may be seen in hospitalized patients for various reasons. Rapid remineralization of bone after surgery for primary hyperparathyroidism (hungry bone syndrome), treatment for hyperthyroidism, or treatment for hematological malignancy may result in hypocalcemia. Acute hemorrhagic or edematous pancreatitis is frequently complicated by hypocalcemia. Vitamin D deficiency may also be associated with hypocalcemia because of impaired intestinal absorption of calcium and skeletal resistance to PTH. Osteomalacia and rickets are discussed in a later section of this chapter.

Clinically, hypocalcemia most commonly presents with neuromuscular hyperexcitability, such as tetany, paresthesia, and seizures. A rapid fall in the serum calcium also may be associated with hypotension and electrocardiographic abnormalities.

The initial laboratory evaluation is directed toward the assessment of renal function and measurement of serum albumin and magnesium concentrations. Serum intact PTH concentrations are low or inappropriately normal in hypoparathyroidism and elevated in pseudohypoparathyroidism. Vitamin D deficiency is characterized by low serum 25(OH)D, high PTH (secondary hyperparathyroidism), and high serum alkaline phosphatase (ALP).

For symptomatic hypocalcemia, calcium may be administered intravenously. If hypocalcemia is secondary to hypoparathyroidism or pseudohypoparathyroidism, vitamin D and oral calcium supplements are administered.

An unusual and treatment-resistant form of symptomatic hypocalcemia is seen in patients treated with large amounts of burn cream that contains polyethylene glycols. The glycols are absorbed and metabolized to dicarboxylic acids that bind calcium. Patients develop markedly increased total calcium and decreased free calcium, along with a metabolic acidosis and increased serum osmolality from the glycols.

BOX 49-2 Differential Diagnosis of Hypercalcemia

- Primary hyperparathyroidism
  - Adenoma, hyperplasia, carcinoma
  - Familial
  - Multiple endocrine neoplasia type I with pituitary and pancreatic tumors
  - Multiple endocrine neoplasia type II with medullary thyroid carcinoma and pheochromocytoma
- Malignancy
  - With skeletal involvement
    - Direct tumor erosion of the bone
    - Local tumor production of bone-resorbing agents
  - No skeletal involvement (humoral hypercalcemia of malignancy)
    - Parathyroid hormone–related protein
    - Growth factor(s) (tumor growth factor, epidermal growth factor, platelet-derived growth factor)
  - Hematological malignancy
    - Cytokines (interleukin-1, tumor necrosis factor, lymphotoxin)
    - 1,25-Dihydroxyvitamin D (lymphoma)
  - Coexistent primary hyperparathyroidism
- Other endocrine disorders
  - Hyperthyroidism
  - Hypothyroidism
  - Acromegaly
  - Acute adrenal insufficiency
  - Pheochromocytoma
- Familial hypocalciuric hypercalcemia
- Idiopathic hypercalcemia of infancy
- Vitamin overdose
  - Vitamin D
  - Vitamin A
- Granulomatous diseases
  - Sarcoidosis
  - Tuberculosis
  - Berylliosis
  - Coccidioidomycosis
- Renal failure
  - Chronic renal failure
  - Acute renal failure—diuretic phase
  - Post–renal transplantation
- Chlorothiazide diuretics
- Lithium therapy
- Milk-alkali syndrome
- Hyperalimentation regimens
- Immobilization
- Increased serum proteins
  - Hemoconcentration
  - Hyperglobulinemia due to multiple myeloma

Hypercalcemia

Hypercalcemia is commonly encountered in clinical practice[23,41] and results when the flux of calcium into the extracellular fluid compartment from the skeleton, intestine, or kidney is greater than the efflux. For example, when excessive resorption of bone mineral occurs in malignancy, hypercalciuria develops. When the capacity of the kidney to excrete filtered calcium is exceeded, hypercalcemia develops. Hypercalcemia can be caused by increased intestinal absorption (vitamin D intoxication), increased renal retention (thiazide diuretics), increased skeletal resorption (immobilization), or a combination of mechanisms (primary hyperparathyroidism).

Common and many of the uncommon etiologies of hypercalcemia are listed in Box 49-2. Primary hyperparathyroidism is the most common cause in outpatients, whereas malignancy is the most common cause in hospitalized patients. Together, these two disorders account for 90% to 95% of all cases of hypercalcemia.

Primary hyperparathyroidism is characterized by excessive secretion of PTH that results in hypercalcemia.[491] It is most often due to a solitary adenoma (80% to 85% of cases), less frequently (about 15%) due to chief cell hyperplasia involving all glands, and rarely due to parathyroid carcinoma (<1%).

Greater than 80% of hyperparathyroid patients are relatively free of symptoms on presentation because of the early detection of this disorder by the widespread use of chemistry panels, including calcium.[393] The most common signs and symptoms of hypercalcemia are nonspecific and related to the neuromuscular system. They include fatigue, malaise, and weakness with mild hypercalcemia (calcium <12 mg/dL); depression, apathy, and inability to concentrate may be present at higher concentrations. Hypercalcemia may induce mild nephrogenic diabetes insipidus with thirst, polydipsia, and polyuria. Renal colic caused by kidney stones can result from chronic hypercalcemia and hypercalciuria. Nephrocalcinosis can lead to slowly developing renal failure. Osteoporosis is more common than osteitis fibrosa. The majority of patients with primary hyperparathyroidism (>60%) are postmenopausal women.

Primary hyperparathyroidism is diagnosed by laboratory studies. Hypercalcemia should be documented by measuring total calcium and serum albumin, or ideally free calcium, on more than one occasion before initiating further testing. Measurement of intact PTH (with concomitant measurement of calcium) is the most sensitive and specific test for parathyroid function and is central to the differential diagnosis of hypercalcemia. Serum $1,25(OH)_2D$ is usually in the upper half of the reference interval or increased in primary hyperparathyroidism, as PTH stimulates its production. By contrast, $1,25(OH)_2D$ (like PTH) is low-normal or suppressed in nonparathyroid hypercalcemia, except in sarcoidosis, other granulomatous diseases, and certain

lymphomas in which the pathological tissues contain the 25-hydroxyvitamin D-1α-hydroxylase required to produce $1,25(OH)_2D$.

PTH increases the renal clearance of bicarbonate and phosphate. In hyperparathyroidism, a mild hyperchloremic metabolic acidosis may be observed whereas in nonparathyroid hypercalcemia, a mild hypochloremic metabolic alkalosis may be observed. Although hypophosphatemia is often seen in hyperparathyroidism, the measurement of serum phosphate is of limited value because hypophosphatemia is also found in hypercalcemic cancer patients.

Patients with primary hyperparathyroidism with signs or symptoms of hypercalcemia should undergo parathyroid surgery. If the patient is asymptomatic, guidelines have been established recommending surgery over monitoring depending on the serum calcium concentration, creatinine clearance, urine calcium, and bone density.[42]

Hypercalcemia occurs in 10% to 20% of individuals with cancer. Tumors most commonly cause hypercalcemia by producing PTHrP, which is secreted into the circulation and stimulates bone resorptions and/or by invasion of the bone by metastatic tumor, which produces local factors that stimulate bone resorption. PTHrP binds to the PTH receptor and is the principal mediator of humoral hypercalcemia of malignancy (HHM). Cytokines such as lymphotoxin, interleukin-1, tumor necrosis factor, and PTHrP appear to be important mediators of hypercalcemia in multiple myeloma and other hematological malignancies. Some lymphomas associated with acquired immunodeficiency syndrome or HTLV I infections cause hypercalcemia by producing $1,25(OH)_2D$. It is estimated that 5% of patients with hypercalcemic cancer have coexisting primary hyperparathyroidism.

Signs and symptoms of hypercalcemia are often evident in patients with hypercalcemia due to malignancy, because the serum calcium increases rapidly and often reaches concentrations higher than those usually seen in primary hyperparathyroidism. Lethargy, obtundation, nausea, and vomiting are additional symptoms.

Laboratory test selection is similar to that in suspected hyperparathyroidism, with the addition of PTHrP in some individuals with HHM. In specific instances (for example, lymphoma), measurement of $1,25(OH)_2D$ may be useful.

Therapies are directed toward treating the malignancy, decreasing the serum calcium concentration by saline diuresis, and decreasing osteoclastic resorption (bisphosphonates, calcitonin, etc.). Steroids are useful in reducing intestinal absorption of calcium in $1,25(OH)_2D$-mediated hypercalcemia.

Measurement of Calcium

The methods most widely used for quantifying calcium measure either free (ionized) calcium or total calcium. The term *ionized calcium* is a misnomer because all plasma or serum calcium is ionized whether or not it is associated with protein or small anions by ionic binding. Throughout this chapter, we use the term *free calcium*, analogous to free hormones (e.g., free thyroxine or free testosterone).

Free calcium is considered the best indicator of calcium status, because it is biologically active and tightly regulated by PTH and $1,25(OH)_2D$. Although the measurement of free calcium is clinically more useful, it has not replaced the measurement of total calcium. Although an ion-specified electrode (ISE) method is available on large chemistry analyzers from one manufacturer, the ISE has not been implemented in a way to measure free calcium. Nonetheless, free calcium determinations have assumed increasing importance, because of the availability of improved analyzers (that typically measure free calcium, other electrolytes, blood gases, hemoglobin, and glucose) and more convenient methods for specimen handling. They are recommended for all requests for calcium apart from chemistry panels, because of the consequences of delayed treatment and the cost of working-up patients with misleading total calcium results.[67]

Adjusted or Corrected Total Calcium

The recognition that serum proteins, particularly albumin, and organic and inorganic ions affect total calcium concentrations has resulted in the concept of adjusting or correcting serum total calcium concentrations. Although various calculations have been proposed for adjusting total calcium results to correct for alterations in total protein, albumin, globulin, pH, anion gap, bicarbonate, and other calcium-complexing ions,[283,409] only adjustments based on albumin are widely used. The term "adjusted calcium" may be preferable to the more widely used "corrected calcium," because "corrected" may suggest the result has been corrected because of an error.

Adjusted calcium is calculated from total calcium and albumin by first calculating a correction factor by multiplying the deviation of plasma albumin from the mean of its reference interval by the slope of the regression of total calcium against albumin. The following equation is often seen in textbooks, but fails to consider the lack of harmonization of albumin and calcium methods, and differences in patient populations:

$$\text{Corrected total calcium (mg/dL)} = \text{Total calcium (mg/dL)} + 0.8(4 - \text{albumin [g/dL]})$$

Evidence suggests that it is inappropriate to adjust calcium data in one laboratory with equations derived in other laboratories.[20,283] Laboratories can establish their own equations for correcting total calcium by determining the slope of the regression of total calcium against albumin and the mean of their albumin reference interval in selected or unselected groups of patients and normal persons.[20,283,533,562,602] This is especially important if the laboratory is reporting corrected calcium, a practice that may be more common outside the United States. Because regression equations vary between individuals and among groups of patients in different physiological and pathological states,

BOX 49-3 Factors Altering the Distribution Between Protein-Bound, Complexed, and Free Calcium and Compounding the Interpretation of Total Calcium

Factors Altering Protein Binding of Calcium
- Altered concentration of albumin or globulins
- Abnormal proteins
- Heparin
- pH
- Free fatty acids
- Bilirubin
- Drugs
- Temperature

Factors Altering Complex Formation
- Citrate
- Bicarbonate
- Lactate
- Phosphate
- Pyruvate and β-hydroxybutyrate
- Sulfate
- Anion gap

mathematical corrections are only approximations. Some factors complicating the interpretation of total calcium and limiting the effectiveness of these equations are pH effects on calcium binding to protein, variation in binding kinetics, free and albumin-bound fatty acids,[621] substances and drugs that are bound by albumin, unusual quantities or types of serum proteins, heparin, and anions complexing calcium (Box 49-3).

Corrections have been applied with some success in patients who have liver disease and low concentrations of protein, but less successfully in patients with renal failure.[297] Their value in hypercalcemia and in specimens with increased proteins because of venous occlusion has been questioned.[283] Several studies have questioned the value of adjusting total calcium values,[319,533,562,602] and one[319] showed that adjusted calcium results were no better than total calcium in predicting free calcium. Equations that are derived for a specific patient group, such as patients with liver disease, may be better than no correction in that group of patients.

When possible, mathematical adjustments or corrections should be replaced by direct determination of free calcium by ISE.

Measurement of Total Calcium

Many methods have been used historically to measure total calcium.[7,252,283,469,597] Today, only photometric, ISE, and occasionally atomic absorption spectrophotometry methods are routinely used by clinical laboratories for the measurement of serum and urine total calcium. According to the College of American Pathologists Comprehensive Chemistry Survey, in 2004 approximately 79% of participating clinical laboratories used photometric methods (35% arsenazo III and 44% cresolphthalein complexone) and 20% of laboratories used ISE methods for total serum calcium.

ISEs for the measurement of total calcium were introduced more recently than photometric methods. The specimen is acidified to convert protein-bound and complexed calcium to free calcium before measurement of calcium by ISE. Calcium ISEs are discussed later in this chapter.

Photometric and atomic absorption spectrophotometric methods for measuring the total calcium in serum and plasma are described and discussed below.

Photometric Methods

Total calcium is most frequently measured by spectrophotometry using metallochromic indicators or dyes. Of the metallochromic indicators that change color on selectively binding calcium, *o*-cresolphthalein complexone (CPC) (3′,3″-bis[[bis-(carboxymethyl)amino]-methyl]-5′,5″-dimethylphenolphthalein) (Figure 49-3) and arsenazo III are most widely used. These methods, although less accurate and reproducible than atomic absorption spectrophotometry, have been easier to automate on chemistry analyzers.

o-Cresolphthalein Complexone Method. In alkaline solution, the metal-complexing dye CPC forms a red chromophore with calcium, which is usually measured at a wavelength between 570 and 580 nm.[118,220,299,347,539] The sample is diluted with acid to release protein-bound and complexed calcium. Organic base, most often diethylamine, 2-amino-2-methyl-1-propanol, or 2-ethylaminoethanol, is added to buffer the reaction and to produce an alkaline pH.[185,384] Interference by magnesium ions can be reduced by (1) the addition of 8-hydroxyquinoline (see Figure 49-3); buffering the reaction mixture to near pH 12; and (3) measurement of the absorbance near 580 nm.[118,220,592] Urea may be added to reduce the turbidity of lipemic specimens and enhance complex formation.[220,299] The use of cyanide has been questioned.[107,159] Ethanol or other organic solvents may be included to reduce blank absorbance.[347] Calcium forms both 1:1 and 2:1 complexes with CPC, with the 1:1 complex predominating at lower concentrations.[122] Because the 1:1 complex has a lower molar absorptivity, calibration curves are nonlinear at low calcium concentrations. Multipoint calibration of CPC methods has been recommended. Linearity may be improved by adding sodium acetate.[124] Temperature is carefully controlled, because the reaction is temperature-sensitive.

Arsenazo III Method. Arsenazo III (1,8-dihydroxynaphthalene-3,6-disulfonic acid-2,7-bis[azo-2]-phenylarsonic acid)* (see Figure 49-3), at mildly acidic pH, has much higher affinity for calcium than magnesium. A reaction pH of about 6 is commonly used. Imidazole has been used to buffer the reaction. The solution must be thoroughly

*References 29, 326, 378, 386, 417, 504.

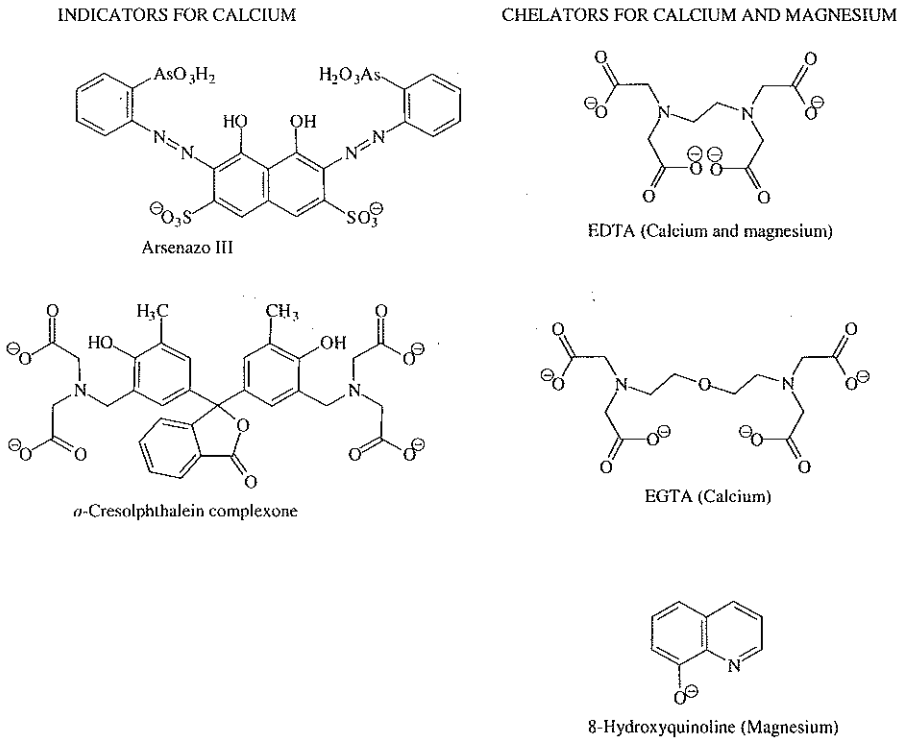

Figure 49-3 Metallochromic indicators for calcium and chelators for calcium and magnesium.

buffered, because the spectral properties of arsenazo III are dependent on pH. Binding of calcium to arsenazo III can be influenced by buffer and sodium concentration.[29] Interference from most biological pigments is reduced by measuring the calcium-dye complex near 650 nm. Citrate has been reported to cause negative interference with the Vitros dry-slide technique.[33,214] Clinically significant interference may be noted in patients receiving citrated blood or blood products. Unlike CPC, a reagent that has limited stability when used as a single reagent, arsenazo III reagent is stable.

Atomic Absorption Spectrometry Methods

The National Committee for Clinical Laboratory Standards (NCCLS) has approved a method using atomic absorption spectrophotometry (AAS) as a reference method for measuring total serum calcium.[398] This method has been compared with isotope dilution-mass spectrometry (ID-MS), the definitive method for total serum calcium developed by the National Institute of Standards and Technology. The reference method is reported to have an accuracy of 100 ± 2%, compared with 100 ± 0.2% for ID-MS.[93] Although AAS can provide better accuracy and precision for total serum calcium than the widely used photometric methods, it is used by only a few laboratories. It should continue to be used for validating new total calcium methods.

In this method, the specimen is first diluted 1 to 50 with a solution of lanthanum-HCl ($LaCl_3$, 10 mmol/L; HCl, 50 mmol/L) and then aspirated into an air-acetylene flame, where the ground state calcium atoms absorb incident light from a calcium hollow-cathode lamp (422.7 nm). The amount of light absorbed is measured by a phototube or detector after the 422.7-nm resonance line is isolated with the monochromator. Absorbance is directly proportional to the number of ground state calcium atoms in the flame. Detailed procedures[68,93,446,598] for the determination of total calcium in serum and reviews[68,469] of this method have been published.

Dilution with lanthanum-HCl reduces interference from protein, phosphate, citrate, sulfate, and other anions. Phosphate causes the greatest interference because calcium-phosphate complexes are not dissociated readily by the air-acetylene flame. Lanthanum-HCl dissociates complexes, ensuring that all fractions of calcium (free, protein-bound, and complexed) are measured. Dilution effectively reduces the viscosity, which can also interfere by reducing the aspiration rate and atomization of the specimen.

The effect of the three major cations, Na^+, K^+, and Mg^{2+}, is offset by their inclusion in calibrators at normal serum concentrations. An automated diluter is recommended because the imprecision (expressed as the coefficient of variation [CV]) for measurements of total calcium should be less than 1.5% and preferably less than 1%. A serum-based calibrator with calcium concentration determined by ID-MS is available commercially.

Strontium may be included in the diluent to be used as an internal standard with double-beam spectrophotometers.[446] The signal from calcium is referenced to the simultaneously measured strontium signal, thereby reducing variability caused by fluctuations in the flame and atomization rate.

Specimen Requirements

Serum and heparinized plasma are the preferred specimens. Citrate, oxalate, and ethylene diamine tetraacetic acid (EDTA) anticoagulants should not be used for the spectrophotometric methods, because they interfere by forming complexes with calcium. Total calcium measurements are not affected by storage provided the loss of water associated with prolonged refrigerator or freezer storage is prevented (by use of tightly capped containers designed for such storage). Co-precipitation of calcium with fibrin (for example, in heparinized plasma) or lipids has been reported with storage or freezing.[112,223] Plastic[238] and glass may adsorb calcium from dilute solutions during storage.

Interferences

Hemolysis, icterus, lipemia,[221,222] paraproteins, and magnesium have been reported to interfere either positively or negatively with photometric methods. Many methods use bichromatic analysis or multiwavelength corrections, or blanking to reduce interference. Lipemic specimens should be ultracentrifuged before analysis. Although hemolysis can cause a negative error because red blood cells contain lower concentrations of calcium than does serum, more significant errors may be caused by the spectral interference of hemoglobin. Depending on the method, hemoglobin has been reported to produce either negative or positive interference.[103,121] In photometric methods, if hemolyzed specimens must be analyzed, blanking with ethylene glycol-O,O′-bis(2-aminoethyl)-*N,N,N′,N′*-tetraacetic acid (EGTA)-treated serum is suggested. Individual instruments and methods should be evaluated for their susceptibility to interference from magnesium, hemoglobin, bilirubin, turbidity, and other interferents.

Care should be taken in handling specimens, calibrators, and solutions to prevent contamination with calcium. Any glassware or plastic ware that is reused should be washed with dilute hydrochloric acid (HCl), followed by distilled water, to eliminate calcium contamination. Corks should not be used because they can contaminate specimens with calcium.[532]

How the patient is prepared and the specimen is obtained can have a significant effect on both free and total calcium measurements. For information on these preanalytical effects, the reader is directed to a later section in this chapter on the subject and to Box 49-4.

BOX 49-4 Preanalytical Factors in Measurement of Serum Total or Free Calcium

In Vivo

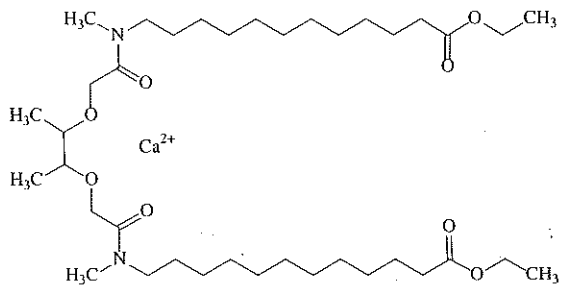
Tourniquet use and venous occlusion
Changes in posture: 10% to 12% increase of total calcium and 5% to 6% increase of free calcium on standing
Exercise
Hyperventilation
Fist clenching
Alimentary status
Alterations in protein binding (see Box 49-3)
Alterations in complex formation (see Box 49-3)

In Vitro

Inappropriate anticoagulants
Dilution with liquid heparin
Interfering levels of heparin
Contamination with calcium
  Corks, glassware, tubes
Specimen handling
  Alterations in pH (free calcium)
  Adsorption or precipitation of calcium
Spectrophotometric interference
  Hemolysis, icterus, lipemia

Measurement of Free (Ionized) Calcium (See also Chapter 27.)

Analyzers using ISEs capable of providing immediate whole-blood determinations of free calcium, electrolytes, and blood gases are now widely available.* The free calcium analyzer consists of a system of pumps under microprocessor control that transport calibration solutions, samples, and wash solutions through a measuring cell containing calcium ion-selective, reference, and pH electrodes. Sensitive potentiometers measure the voltage difference between the calcium or pH and reference electrodes for calibrating solutions or samples. A microprocessor calibrates the system and calculates calcium concentration and pH. Most instruments simultaneously measure the actual free calcium and pH at 37 °C.



Calcium ISEs contain a calcium-selective membrane, which encloses an inner reference solution of calcium chloride often containing saturated silver chloride (AgCl) and physiological concentrations of sodium chloride and potassium chloride (KCl) and an internal reference electrode.* The reference electrode, usually of Ag/AgCl, is immersed in this inner reference solution.

Modern calcium ISEs use liquid membranes containing the ion-selective calcium sensor dissolved in an organic liquid trapped in a polymeric matrix. Neutral carriers (for example, ETH 1001) are the most commonly used calcium sensors, followed by ion exchangers, such as organophosphate sensors (Figure 49-4). Neutral carrier membranes contain an uncharged calcium-selective organic molecule, such as ETH 1001, dissolved in a plasticizer and trapped in a polyvinyl chloride membrane. These molecules have a favorable stearic and electrostatic pocket or site for selectively binding calcium. Ion exchangers or negatively

charged carrier membranes are calcium salts, usually calcium bis(di-*n*-octylphenyl) phosphate dissolved in di-*n*-octylphenyl phosphonate and trapped in a polyvinyl chloride membrane.

The electrochemical cell is completed by the external reference electrode, an Ag/AgCl or calomel electrode, which is in contact with the specimen by a liquid/liquid junction or salt bridge of KCl or sodium formate. The potential difference across the cell is logarithmically related to the activity of free calcium ions in the sample by Nernst's equation. By convention, free calcium is converted from activity to concentration with its activity coefficient, which is itself dependent on ionic strength.

Temperature affects electrode response and the extent of calcium binding by protein and small anions. Most free calcium analyzers adjust and maintain samples at 37 °C, thereby ensuring that results are physiologically relevant for the majority of patients.

Carryover has been minimized with the use of flush solutions containing 5.0 mg/dL (1.25 mmol/L) of free calcium, by using the leading edge of the specimen to clean the fluid path, or by purging with air.[81] Significant carryover is noted only at extremely low or high concentrations of free calcium.

The International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) has recommended a reference method for free calcium.[85]

Interferences

Because ISEs measure ion activity, they are affected by the ionic strength of a specimen. Free calcium analyzers and calibrators are optimized for specimens of serum, plasma, or whole blood. Because the ionic strength of these fluids is primarily a result of Na^+ and Cl^-, calibrators are usually prepared in buffer and NaCl with a final ionic strength of 160 mmol/kg.[56,81,123,515] Although the range of Na^+ and Cl^- concentrations usually observed in serum or plasma does not cause a clinically significant error in the measurement of free calcium, significant errors can occur with other specimens unless the matrices and ionic strength of the calibrators and samples are matched closely.

Modern electrodes have a high selectivity for calcium over Na^+, K^+, Mg^{2+}, H^+, and Li^+.[81,567] At normal concentrations, these cations have little effect on the accuracy of free calcium measurements. Wide variations in the concentration of Na^+ and high concentrations of Mg^{2+} and Li^+ may influence the apparent concentration of free calcium. Electrodes are quite insensitive to H^+, with insignificant interference between pH 5 and 9.

Many physiological anions, including protein, phosphate, citrate, lactate, sulfate, and oxalate, form complexes with calcium ions. Although these anions reduce the concentration of free calcium by complex formation, they do not directly interfere with the measurement of the calcium that is free. Protein deposits on the electrode may act as a divalent cation exchanger, resulting in positive interference with high concentrations of Mg^+.[81] Older electrodes were sensitive to the concentration of protein in the sample. The newer electrodes use a dialysis membrane or neutral carrier to reduce or eliminate this protein effect.[81,370,416,428,559] Investigators disagree about whether the relationship between free calcium and protein concentration is a consequence of Donnan's equilibrium or a protein effect. With current electrodes, the effect is less than +0.02 mmol/L for 1 g/dL (10 g/L) of protein. Regular instrument maintenance and protein removal are reported to minimize this interference.

Chemicals may interfere in the measurement of free calcium. Anionic surfactants and ethanol have been reported to affect the calcium-selective membrane.

Effect of pH

The binding of calcium by protein and small anions is influenced by pH in vitro and in vivo.[81,559] Albumin, with up to 30 binding sites for calcium,[189,314] accounts for approximately 80% of the protein-bound calcium. Increasing the pH of a specimen in vitro increases the ionization and negative charge on albumin and other proteins, leading to an increase

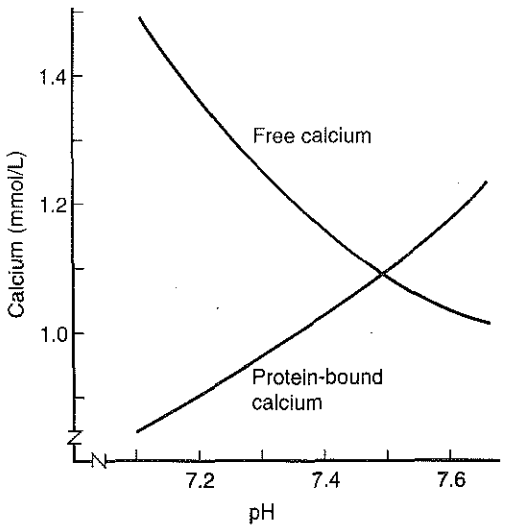

Figure 49-5 Effect of pH on free and protein-bound calcium.

in protein-bound calcium and a decrease in free calcium. Decreasing pH in vitro decreases ionization and negative charge, decreasing protein-bound calcium and increasing free calcium. Free calcium changes by about 5% for each 0.1-unit change in pH (Figure 49-5).

Because of this inverse relationship between free calcium and pH, specimens must be analyzed at the patient's pH in vivo, requiring that all specimens be handled to prevent alterations in pH.

Specimen Requirements

Preanalytical considerations, including specimen collection and handling, are particularly important for free calcium. Specimens for free calcium must be collected and handled to minimize alterations in pH and free calcium by (1) loss of CO_2 and (2) metabolism by blood cells. Free calcium may be measured in heparinized whole blood, heparinized plasma, or serum. For the majority of laboratories in which specimens are analyzed within minutes of sampling using blood gas analyzers, heparinized whole blood is preferable since it reduces processing time and the required specimen volume and avoids the alteration in pH associated with centrifugation. All syringes and evacuated tubes should be filled completely, kept tightly sealed, and handled anaerobically to prevent the loss of CO_2 and the increase in pH that occurs when specimens are exposed to air. Specimens should also be handled to prevent a decrease in pH caused by the production of lactic acid by glycolysis, by erythrocytes, and by white blood cells. The NCCLS has published guidelines for free calcium specimen collection and handling.[400]

Ideally, whole blood specimens should be analyzed within 15 to 30 minutes of sampling, although free calcium is reported to be stable in whole blood specimens for at least 1 hour at room temperature and for 4 hours at 4 °C.* If specimens cannot be analyzed within minutes, they can be collected in an ice-water slurry to minimize metabolism, but plasma K^+ concentrations may be significantly increased because of the inhibition of ATPase. One study[187] reported that K^+ was significantly increased after 1 hour at 4 °C, the earliest time investigated; no change was apparent for any other analytes for as long as 2 hours at 4 °C.

If analysis cannot be completed within 30 to 60 minutes at room temperature, then serum may be the optimal specimen because of elimination of the anticoagulant and microclots and its greater stability. Serum specimens should be collected in evacuated gel tubes.[324,570] The tubes should be filled completely and centrifuged to form an effective barrier between the serum and the clot with its cellular elements. Once centrifuged, specimens are stable for hours at 25 °C and for days at 4 °C, provided the tube remains sealed. Free calcium has been reported to be less stable in specimens from both acidotic and nonacidotic patients with uremia.[408]

The practice of using aerobic specimens for the measurement of free calcium should be abandoned because of the widespread availability of blood gas analyzers measuring free calcium and the use of evacuated gel tubes by reference laboratories. In the past, specialized free calcium analyzers equilibrated aerobic specimens with a carbon dioxide (5.3 kPa) air mixture to adjust their pH to near 7.4 (7.2-7.6), and then mathematically corrected the free calcium to pH 7.4, using an algorithm relating free calcium and pH.[81,188,559] In the event that aerobic free calcium results are corrected to pH 7.4 after equilibration with a mixture of CO_2 and air, only the free calcium at pH 7.4 should be reported with appropriate identification. The normalized or adjusted free calcium at pH 7.4 has been reported to accurately reflect the free calcium status of normal persons and individuals without acid-base disturbances.[81,559,561] However, aerobic handling of specimens with correction of the free calcium to pH 7.4 has been increasingly criticized.[81,494,558,594] The free calcium value at pH 7.4 may be misleading in patients with respiratory and metabolic alkalosis or acidosis.[408] Furthermore, aerobic handling of specimens has been associated with irreversible precipitation of calcium-phosphate complexes and a decrease in free calcium in some specimens having a high total calcium and phosphate content or a high pH (pH > 7.9).[559]

Effects of Anticoagulants

Because citrate, oxalate, and EDTA bind calcium and significantly reduce free calcium, heparin is the only acceptable anticoagulant for free calcium determinations. However, heparin, a polyanion, significantly lowers free calcium at the concentrations (30 to 100 U/mL or more) found in many conventional blood gas syringes (Table 49-3).[86,402,495,496,567] In addition, the use of liquid heparin should be avoided; it can result in errors in free calcium because of dilution, as well as high and variable concentrations of heparin.

A number of commercially available syringes containing lyophilized heparin are suitable for free calcium-determinations: (1) electrolyte-balanced or calcium-titrated heparin

*References 57, 81, 498, 559, 560, 570.

TABLE 49-3 Effect of Heparin on Free Calcium

Specimen	Heparin (U/mL)	Free Calcium (mg/dL)	Free Calcium (mmol/L)
Serum	0	5.00	1.25
Plasma	44 (Ca-heparin)	4.96	1.24
Plasma	29 (Na-heparin)	4.84	1.21
Plasma	100 (Na-heparin)	3.76	0.94
Whole blood	44 (Ca-heparin)	5.08	1.27
Whole blood	19 (Na-heparin)	5.04	1.26
Whole blood	100 (Na-heparin)	3.88	0.97

Modified from Toffaletti J. Ionized calcium. In: Pesce AJ, Kaplan LA, eds. Methods in clinical chemistry. St. Louis: CV Mosby, 1987:1010-20.

syringes (final concentration of 40 to 50 U/mL); (2) very low heparin syringes with heparin in an inert filler, providing a final heparin concentration of 2 to 3 U/mL; and (3) lithium-zinc heparin syringes.[572] With electrolyte-balanced or calcium-titrated heparin syringes, the heparin is titrated with calcium so that the free calcium is not significantly altered over most observed concentrations (3.6 to 6.4 mg/dL [0.9 to 1.6 mmol/L]); however, some bias may be apparent at very low and high free calcium concentrations. Electrolyte-balanced heparin may also produce a bias in specimens with pathologically low protein concentrations.[350] In the very low heparin syringes that contain 2 to 3 U/mL of heparin dispersed in a puff of inert proprietary material, the puff allows the heparin to be accurately dispensed during manufacturing and rapidly dissolve with proper mixing, providing effective anticoagulation. A blend of lithium and zinc heparins has been reported to eliminate the heparin interference in free calcium measurements.[322,548,574] In addition, lithium-zinc heparin did not alter total calcium, unlike electrolyte-balanced or calcium-titrated heparin. Three-milliliter syringes containing a total of 50 U of a 1:1 blend of lithium and zinc heparins did not alter results of any general chemistry tests except total magnesium, which was increased by 0.19 mg/dL (0.08 mmol/L). In no instance should the individuals obtaining the blood specimen add additional liquid heparin to heparinized syringes.

Most evacuated collection tubes, when filled completely, contain concentrations of heparin (15 U/mL) that only slightly decrease free calcium.[568] Specific brands of syringes, evacuated tubes, and heparin should be carefully evaluated. It is important that all syringes and tubes be filled completely to minimize dilution and/or heparin effects.

Calibrators and Quality Controls

Various calibration solutions are used by manufacturers for free calcium analyzers. The buffers in which these calibrations are prepared may have an effect on the liquid junction potential and calcium binding; however, it is usually corrected for by the instrument software.[81] Until reference solutions are available, it is best to use the calibrators provided by the instrument manufacturer.

Aqueous quality control materials are commercially available for free calcium. Because simple aqueous controls may not reliably detect changes in performance with patient specimens, serum-based quality control materials should be used daily.[198,573] Serum-based controls may be prepared by acidifying serum with 10 μL of 1 mol/L HCl and leaving it exposed in the refrigerator for 1 week to remove carbon dioxide. The pH is then adjusted to 7.4, and the serum is aliquoted and frozen. Alternatively, serum-based controls can be equilibrated with carbon dioxide before their analysis.

Patient Preparation and Sources of Preanalytical Error for Total and Free Calcium Measurements

Patient preparation and the manner of specimen collection can significantly alter the results of total and free calcium determinations (see Box 49-4).[81,230,469,498,559]

A common and important source of preanalytical error in the measurement of calcium is the increase in total, but not free, calcium concentration associated with tourniquet use and venous occlusion during sampling.[461,469] Errors of 0.5 to 1.0 mg/dL (0.12 to 0.25 mmol/L) in total calcium may result because of the increase in protein-bound calcium caused by the efflux of water from the vascular compartment during stasis. Only small and clinically insignificant increases in free calcium have been reported with venous stasis. If a tourniquet is required, it should be applied just before sampling and released as soon as possible.

Fist clenching or other forearm exercise should be avoided before phlebotomy, because forearm exercise causes a decrease in pH (lactic acid production) and an increase in free calcium. The NCCLS and IFCC have published recommendations on blood collection.[86,399]

Changes in posture cause fluid shifts within 10 minutes and thus alter the concentration of cells and large molecules, including albumin and total calcium (as part of it is protein-bound) in the vascular compartment. Standing decreases intravascular water and increases the total calcium concentration by 0.2 to 0.8 mg/dL (0.05 to 0.20 mmol/L), whereas

a much smaller effect has been reported for free calcium.* One partial explanation (along with hypoalbuminemia) for the mild hypocalcemia observed in many hospital patients may be the hemodilution associated with recumbency.

Most other preanalytical factors are less likely to lead to confusion. Prolonged immobilization and bed rest[250,540] can decrease bone density and increase total and free calcium. Hyperventilation and exercise decrease and increase the concentration of free calcium, respectively, because of changes in serum pH.[81,461,469] Both serum free calcium and calcium excretion are lower during the night.[95] Food ingestion has been reported to have various effects, but usually causes a mild increase in serum calcium. Ingestion of calcium salts may increase serum calcium. Hemolysis can alter free calcium because of dilution and alterations in pH and binding (see previous discussion under Interferences). Prolonged contact with blood cells may decrease plasma calcium.

Reference Intervals for Total and Free Calcium in Serum and Plasma

Total Calcium

The reference interval for serum and plasma is usually defined by an upper limit of 10.1 to 10.3 mg/dL (2.54 to 2.57 mmol/L) and a lower limit between 8.6 and 8.8 mg/dL (2.15 to 2.20 mmol/L). Although higher upper limits of 10.5 to 11.0 mg/dL (2.62 to 2.74 mmol/L) have been used by some laboratories, it is now appreciated that these concentrations are inappropriately high.[283]

Adults: 8.6 to 10.2 mg/dL (2.15 to 2.55 mmol/L)

An analytical goal, or quality specification, for between-day imprecision, expressed as the CV, is 0.9% or less based on within-person biological variation.[192] Current methods are capable of achieving a between-day CV of 1.5% or less.

Free Calcium

The reference interval established by the author at LAC+USC Medical Center using whole blood is representative of free calcium reference intervals:

Adults: 4.6 to 5.3 mg/dL (1.15 to 1.33 mmol/L).

Because of the dependence of free calcium on pH, it is recommended that pH be measured and reported with all free calcium determinations. This will assist the laboratory and physician in identifying specimens in which inappropriate preanalytical handling has led to an in vitro change in pH. Correction of the free calcium to pH 7.4 may be inappropriate and confusing to the physician.

Whole blood specimens develop a liquid-junction potential different from that of serum or plasma because of the presence of erythrocytes.[81,416,559] A positive bias that is directly proportional to the hematocrit has been reported. In addition, free calcium values have been reported to differ among capillary blood, venous blood, and serum samples because of differences in pH. Therefore, reference intervals should be determined by each laboratory using the local instrument, specimen type, and collection protocol and reference subjects representative of their patient population.

*References 81, 230, 275, 460, 469, 559.

Physiological Variation in Calcium

Calcium has been reported to vary with age, gender, and season and during pregnancy.[469] Total and free calcium have been reported both to decline modestly and to remain unchanged in the elderly.[522] We were unable to find an age-related decline or a gender-related difference in either total or free calcium values in a healthy ambulatory group of men and women residing in the Southwest.[171] During pregnancy, the total calcium declines in parallel with serum albumin, whereas free calcium is unchanged.[132,434] The fetal circulation is relatively hypercalcemic, as evidenced by higher total and free calcium in cord blood than in maternal serum. Calcium concentrations decline after birth in healthy term neonates during the first few days, but soon rise to concentrations slightly greater than those observed in adults.[89,349,484,593]

Interpretation of Total and Free Calcium Results

Calcium status is more accurately determined by measuring free calcium, the tightly regulated, biologically active species.* Interpretation of total serum calcium value is complicated by its association with protein and inorganic and organic ions.[230,283,469] Interpretation of free calcium concentration is less complicated, provided the specimen has been properly obtained, handled, and analyzed. Disagreement between free and total calcium (abnormal total calcium and normal free calcium, or vice versa) values occurs in a high percentage of specimens.[319,533,562,602] One study[562] of 1213 patients suspected of having calcium disorders found disagreement between free calcium and total calcium or corrected calcium values in 18% and 31% of patients, respectively.

Free calcium is far more useful than total calcium determination in hospital patients, especially those undergoing major surgery (Figure 49-6) who have received citrated blood or platelets, heparin, bicarbonate, intravenous solutions, or calcium.† Alterations in blood pH and temperature further reduce the usefulness of total calcium assay in these patients. Rapid measurement of free calcium, blood gases, and potassium permits maintenance of good cardiac function during liver transplant operations and other major operations such as those in which cardiopulmonary bypass is used. Free calcium is more useful than total calcium determination in patients in intensive care because of abnormal protein concentrations and putative circulating factors that alter calcium binding to albumin. Abnormally low free calcium is frequently found in critically ill patients.[25,99,620] A study at one hospital[67] where free calcium has replaced total calcium determinations found that 41% of free calcium concentrations were abnormal in inpatients. Of these, 31% were

*References 67, 87, 232, 311, 358, 567, 571.

†References 81, 87, 232, 283, 469, 559.

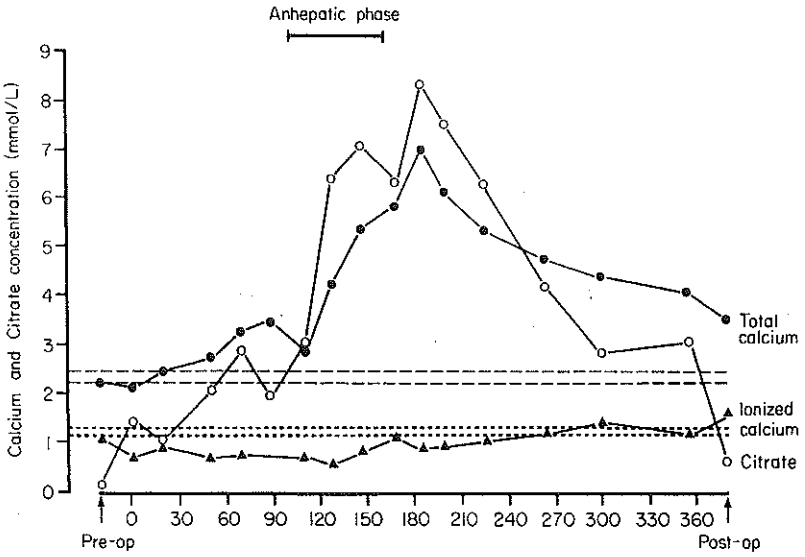

Figure 49-6 Free calcium (▲), total calcium (●), and citrate (○) concentration in a patient undergoing liver transplantation. The reference intervals are indicated by the upper (total calcium) and lower (free calcium) sets of dashed horizontal lines. The reference interval for citrate is 0.03 to 0.15 mmol/L. *(From Gray TA, Paterson CR. The clinical value of ionized calcium assays. Ann Clin Biochem 1988;25:210-9.)*

below and 10% were above the reference interval. The recovery room, surgical intensive care unit, renal transplantation ward, medical intensive care unit, and medical oncology unit had the highest percentages of abnormal values.

Bone and mineral disorders are common in patients with renal disease. Therapy and calcium metabolism of these patients are best evaluated with the determination of free calcium because of alterations in protein, pH, protein binding of calcium, and calcium complexes with organic and inorganic anions. Total and adjusted calcium concentrations are often invalid when compared with free calcium measurements.[87,88,155,297]

Free calcium has proved to be more useful than total calcium in the diagnosis of hypercalcemia.[69,320,323,376] Patients with subsequently surgically proven primary hyperparathyroidism more often have increases of free calcium than of total calcium (Figure 49-7). Free calcium is more sensitive than total calcium in detecting hypercalcemia associated with malignancy, as may be expected in patients who frequently have decreased serum albumin. Less commonly, paraproteins produced in myeloma may bind calcium, complicating the interpretation of total or corrected calcium measurements.

In neonates, the assay of free calcium rather than total calcium is recommended because of its speed and the ability to use small capillary specimens, and because of its greater validity in the presence of hyperphosphatemia, alterations in pH, and the persistence of alpha fetoprotein after birth.[87,232,310,593]

Urinary Calcium

Normal men and women excrete up to 300 mg (7.49 mmol) of calcium per day on a diet with unrestricted calcium content and up to 200 mg/day (4.99 mmol/d) on a calcium-restricted diet (500 mg [12.48 mmol] dietary calcium per day or less for several days).

The reference interval for urinary calcium (UCa) for spot fasting or timed specimens collected after an overnight fast is less than 0.16 mg/100 mL (<0.04 mmol/L) of glomerular filtrate (GF), calculated by the following equation[74]:

$$\text{UCa (mg/100 mL GF)} = \frac{(\text{UCa [mg/dL]}) \times (\text{Serum creatinine [mg/dL]})}{\text{Urinary creatinine (mg/dL)}}$$

The amount of calcium excreted into the urine reflects intestinal absorption, skeletal resorption, and renal tubular filtration and reabsorption.[74] Under fasting conditions, the intestinal and renal components are relatively fixed, and calcium excretion (milligrams per 100 mL of GF) in the fasting state is used to assess the skeletal component. A value exceeding 0.16 mg/100 mL (>0.04 mmol/L) of GF usually implies an increase in osteoclastic bone resorption. This test is useful in assessing renal stone disease and high-turnover osteoporosis.

Calcium salts, such as calcium oxalate, precipitate in urine specimens during and after collection. Specimens may be collected in a container containing acid to prevent calcium salt precipitation. A commonly used acid is HCl, 6 mol/L, with 20 to 30 mL added to the container for a 24-hour collection (1 to 2 mL for a random specimen). The safety of the patient and the patient's family in handling such a container may be a concern. The measured urinary calcium concentration must be corrected for the dilution by the acid solution when the urinary volume is low. The specimen should be kept well mixed during collection. Specimens collected without acid should be acidified and allowed to stand for 1 hour before thorough remixing and aliquoting. Some have questioned the ability of postcollection acidification to redissolve all of the calcium salts with or without heating.[230]

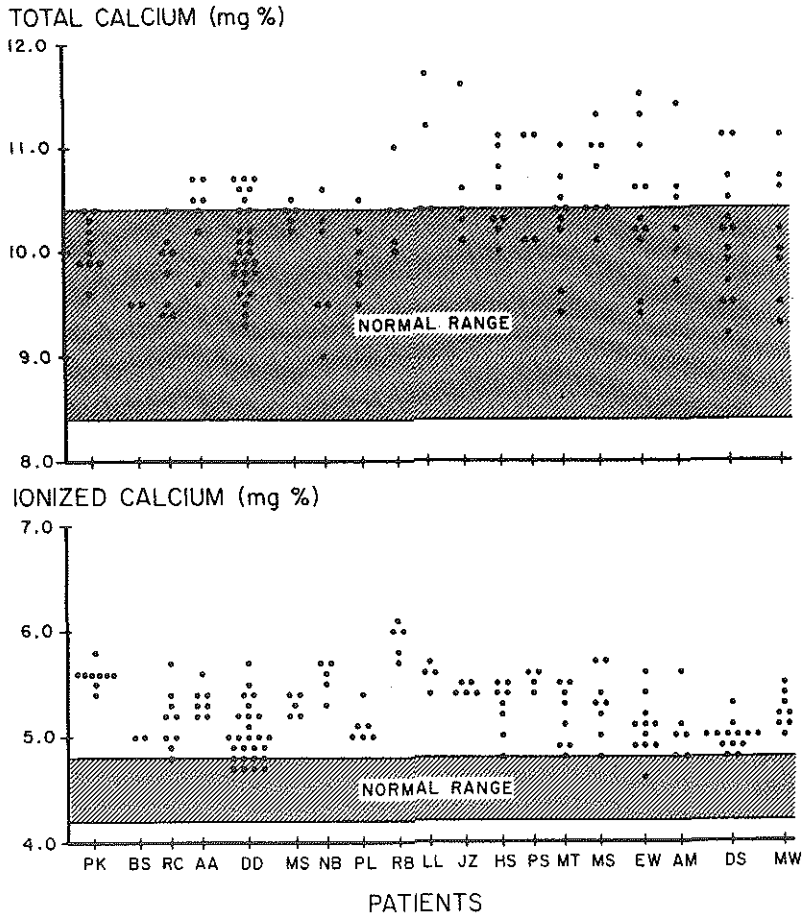

Figure 49-7 Concurrent total and free calcium in patients with primary hyperparathyroidism and intermittent total hypercalcemia. Shaded areas represent the normal reference intervals. *(From McLeod MK, Monchik JM, Martin HF. The role of ionized calcium in the diagnosis of subtle hypercalcemia in symptomatic primary hyperparathyroidism. Surgery 1984;95:667-73.)*

PHOSPHATE

An adult has approximately 600 g (19.4 mol) of phosphorus in inorganic and organic phosphates, of which about 85% is in the skeleton and the rest principally in soft tissue (see Table 49-1).[41,308]

Biochemistry and Physiology

Plasma contains both inorganic and organic phosphate, but only inorganic phosphate is measured. Inorganic phosphate exists as both the monovalent ($H_2PO_4^-$) and divalent (HPO_4^{2-}) phosphate anions. The ratio of $H_2PO_4^-$ to HPO_4^{2-} is pH-dependent and varies from approximately 1:1 in acidosis to 1:4 at pH 7.4 and 1:9 in alkalosis. Approximately 10% of the phosphate in serum is protein-bound; 35% complexed with sodium, calcium, and magnesium; and the remainder, or 55%, is free (see Table 49-2). The organic phosphate esters are located primarily within the cellular elements of blood.

Inorganic phosphate is a major component of hydroxyapatite in bone, thereby playing an important role in the structural support of the body and providing phosphate for the extracellular and intracellular pool.

In the soft tissue, most phosphate is cellular. Although both inorganic and organic phosphate are present in cells, most is organic and incorporated into nucleic acids, phospholipids, phosphoproteins, and "high-energy" compounds involved in metabolism.[618] ATP and other phosphates, such as creatine phosphate, are involved in many energy-intensive physiological functions, such as muscle contractility, neurological function, and electrolyte transport. Phosphate is also an essential element of cyclic nucleotides (such as cyclic AMP) and nicotinamide-adenine dinucleotide phosphate (NADP). It is important for the activity of several enzymes including adenylate cyclase, 25-hydroxyvitamin-D-1α-hydroxylase, and those involved in the production of 2,3-diphosphoglycerate (which regulates the oxygen affinity of hemoglobin). Intracellular phosphate is therefore involved in the regulation of intermediary metabolism of proteins, fats, and carbohydrates, and in gene transcription and cell growth.

Clinical Significance

Disorders of phosphate metabolism are separated into those causing hypophosphatemia and hyperphosphatemia.

Hypophosphatemia

Hypophosphatemia, defined as the concentration of inorganic phosphate in the serum below the normal reference

BOX 49-5 Common Causes of Hypophosphatemia and Phosphate Depletion

- Intracellular shift
  - Glucose
    - Oral or intravenous
    - Hyperalimentation
  - Insulin
  - Respiratory alkalosis
- Lowered renal phosphate threshold
  - Primary or secondary hyperparathyroidism
  - Renal tubular defects
    - Familial hypophosphatemia
    - Fanconi's syndrome
- Decreased net intestinal phosphate absorption
  - Increased loss
    - Vomiting
    - Diarrhea
    - Phosphate binding antacids
  - Decreased absorption
    - Malabsorption syndrome
    - Vitamin D deficiency
- Intracellular phosphate loss
  - Acidosis
    - Ketoacidosis
    - Lactic acidosis

interval, usually less than 2.5 mg/dL (<0.81 mmol/L), is relatively common in hospitalized patients (approximately 2%). Hypophosphatemia is not necessarily associated with intracellular phosphate depletion. Hypophosphatemia may be present when cellular concentrations are normal, and cellular phosphate depletion may exist when serum concentrations are normal or even high.

Hypophosphatemia or phosphate depletion may be caused by (1) a shift of phosphate from extracellular to intracellular spaces, (2) renal phosphate wasting, (3) decreased intestinal absorption, and (4) loss from intracellular phosphate.[308,618] Box 49-5 lists the commonly encountered causes of hypophosphatemia and phosphate depletion.

A shift of phosphate from extracellular fluid to intracellular fluid is a common cause of hypophosphatemia. A major etiology of low serum phosphate is carbohydrate-induced stimulation of insulin secretion, which increases the transport of glucose and phosphate into insulin-sensitive cells, where it is incorporated into sugar phosphates and ATP. Oral or intravenous carbohydrate and injected insulin decrease serum phosphate. Refeeding of malnourished individuals creates an anabolic state, causing an intracellular shift of phosphate. Respiratory alkalosis leads to an increase in intracellular pH, which activates phosphofructokinase and accelerates glycolysis, causing a shift of phosphate into the cell.

Renal phosphate wasting may also cause hypophosphatemia. Any cause of excessive PTH secretion (primary and secondary hyperparathyroidism) lowers the renal phosphate threshold and may result in hypophosphatemia and phosphate depletion. The renal phosphate threshold is also lowered in Fanconi's syndrome, X-linked hypophosphatemic rickets, and tumor-induced osteomalacia.

Hypophosphatemia and phosphate depletion may result from inadequate intestinal phosphate absorption. Patients taking aluminum- or magnesium-containing antacids may develop hypophosphatemia, because these antacids bind phosphate in the intestine, rendering it nonabsorbable. The hypophosphatemia observed in patients with malabsorption may be more closely related to their secondary hyperparathyroidism than to malabsorption of phosphate. Because phosphate is abundant in most foods, dietary deprivation is not usually a cause of phosphate depletion in patients with normal intestinal function and an adequate diet.

Intracellular phosphate may be lost in acidosis as a result of the catabolism of organic compounds within the cell. Diabetic ketoacidosis is associated initially with high-normal to increased serum phosphate. Treatment of the ketosis and acidosis with insulin and intravenous fluids, however, results in a rapid reduction in the serum phosphate concentration. Consequently, patients being treated for diabetic ketoacidosis may have both intracellular phosphate depletion and hypophosphatemia.

The clinical manifestations of serum phosphate depletion depend on the length and degree of the deficiency. Moderate hypophosphatemia of 1.5 to 2.4 mg/dL (0.48 to 0.77 mmol/L) is usually not associated with clinical signs and symptoms (unless chronic, when osteomalacia or rickets develops). Plasma concentrations less than 1.5 mg/dL (0.48 mmol/L) may produce clinical manifestations. Because phosphate is necessary for the formation of ATP, glycolysis and cellular function are impaired by low intracellular phosphate concentrations. Muscle weakness, acute respiratory failure, and decreased cardiac output may occur in phosphate depletion. At very low serum phosphate (<1 mg/dL or <0.32 mmol/L), rhabdomyolysis may occur. Phosphate depletion in erythrocytes decreases erythrocyte 2,3-diphosphoglycerate, which causes tissue hypoxia because of increased affinity of hemoglobin for oxygen. Severe hypophosphatemia (serum phosphate concentration <0.5 mg/dL [<0.16 mmol/L]) may result in hemolysis of the red blood cells. Mental confusion and frank coma also may be secondary to the low ATP and tissue hypoxia. If hypophosphatemia is chronic, impaired mineralization of bone produces rickets in children and osteomalacia in adults.

Treatment of hypophosphatemia depends on the degree of hypophosphatemia and the presence of symptoms. Patients with moderate hypophosphatemia may require only treatment of the underlying disorder or oral phosphate supplementation. In patients with marked symptoms of hypophosphatemia, particularly if respiratory muscle weakness is present, parenteral administration of phosphate may be indicated.

BOX 49-6 Common Causes of Hyperphosphatemia

- Decreased renal phosphate excretion
  - Decreased glomerular filtration rate
    - Renal failure, chronic and acute
  - Increased tubular reabsorption
    - Hypoparathyroidism
    - Pseudohypoparathyroidism
    - Acromegaly
    - Disodium etidronate
- Increased phosphate intake
  - Oral or intravenous administration
  - Phosphate-containing laxatives or enemas
- Increased extracellular phosphate load
  - Transcellular shift
    - Lactic acidosis
    - Respiratory acidosis
    - Untreated diabetic ketoacidosis
  - Cell lysis
    - Rhabdomyolysis
    - Intravascular hemolysis
    - Cytotoxic therapy
    - Leukemia
    - Lymphoma

Hyperphosphatemia

Common causes of hyperphosphatemia are listed in Box 49-6.

Hyperphosphatemia is usually secondary to the inability of the kidneys to excrete phosphate.[308] In acute or chronic renal failure, a decrease in glomerular filtration rate (GFR) reduces the renal excretion of phosphate, resulting in hyperphosphatemia. Moderate increases of serum phosphate occur in individuals with low PTH (hypoparathyroidism), PTH resistance (pseudohypoparathyroidism), or acromegaly (increased growth hormone) caused by an increased renal phosphate threshold. Growth hormone is responsible for the increased renal phosphate threshold and higher phosphate concentrations observed in children. EDTA therapy has also been associated with hyperphosphatemia.

Increased intake and a shift of phosphate from the tissues into the ECF are also causes of hyperphosphatemia. Excessive oral, rectal, or intravenous phosphate administration for the treatment of phosphate depletion is a common cause of hyperphosphatemia. Release of phosphate because of cell breakdown in cases of rhabdomyolysis, intravascular hemolysis, or chemotherapy of certain malignancies may cause hyperphosphatemia. Hyperphosphatemia may also be associated with acidosis, a consequence of the hydrolysis of intracellular organic phosphate-containing compounds, with the release of phosphate into the plasma.

The clinical manifestations of hyperphosphatemia depend on the rate of onset. A rapid increase in serum phosphate may be associated with hypocalcemia. Therefore, symptoms may include tetany, seizures, and hypotension. Long-term hyperphosphatemia may be associated with secondary hyperparathyroidism, osteitis fibrosa, and soft-tissue calcification of the kidneys, blood vessels, cornea, skin, and periarticular tissue.

Therapy for hyperphosphatemia is directed toward correcting the cause of the high serum phosphate. In renal failure and in hypoparathyroidism, dietary restriction of phosphate and agents that bind phosphate in the intestine (calcium carbonate and others) are useful in lowering the serum phosphate concentrations.

Measurement of Phosphate

All widely used methods for serum inorganic phosphate are based on the reaction of phosphate ions with ammonium molybdate to form a phosphomolybdate complex[203] that is then measured by a spectrophotometer.

$$7H_3PO_4 + 12(NH_4)_6Mo_7O_{24} \cdot 4H_2O \rightarrow$$
$$7(NH_4)_3[PO_4(MoO_3)_{12}] + 51NH^{+4} + 51OH^- + 33H_2O$$

The colorless phosphomolybdate complex is measured directly by ultraviolet absorption (340 nm), or reduced to molybdenum blue and measured at 600 to 700 nm.[21,252] An acid pH is necessary for the formation of complexes but must be controlled, because both complex formation and reduction of molybdate are dependent on pH. A less acidic pH can result in spontaneous reduction of molybdate. The rate of complex formation is also influenced by protein concentration. Solubilizing agents are used to prevent protein precipitation. Measurement of unreduced complexes has several advantages, including simplicity, speed, and stability.[16,129,601] Disadvantages include the greater interference of hemolysis, icterus, and lipemia at 340 nm. Approximately 70% of laboratories participating in the College of American Pathologists Comprehensive Chemistry Survey in 2004 used a direct UV procedure, with most of the others using a reduced photometric method.

Many reducing agents have been used for producing the blue phosphomolybdate complex, including aminonaphtholsulfonic acid, stannous chloride, methyl-*p*-aminophenol sulfate, ferrous ammonium sulfate, ascorbic acid, and *N*-phenyl-*p*-phenyldiamine (semidine) HCl.[21,252] Each of these reagents appears to have some individual advantage, such as increased stability, increased color stability, lower detection limit, or reduced hydrolysis of organic esters. Ferrous sulfate and especially ascorbic acid have often been used for biological specimens containing organic esters, because they cause less breakdown of labile phosphate esters. Aminonaphtholsulfonic acid has been widely used but is unstable, tends to precipitate, and requires careful timing because color continues to increase for several hours. With this reagent, color formation is increased with heating. Stannous chloride provides greater color intensity. Hydrazine has been added to stannous chloride to stabilize the reagent and improve the linearity. Methyl-*p*-aminophenol sulfate is

acid-tolerant, allowing for a one-component acid-molybdate reagent. A method using semidine HCl was published as a "Selected Method" by the American Association for Clinical Chemistry.[203]

Phosphate concentrations have been determined by a number of other procedures, including the vanadate-molybdate and enzymatic methods. Vanadate and molybdate form a yellow complex with phosphate at acid pH, but the method tends to overestimate inorganic phosphate because of hydrolysis of organic esters.[252] Enzymatic methods do not have this problem, because they are performed at a neutral pH that does not hydrolyze organic esters. A number of enzymatic methods have been described, including those using the following enzymes: (1) glycogen phosphorylase, phosphoglucomutase, and glucose-6-phosphate dehydrogenase, with monitoring of the formation of the reduced form of nicotinamide-adenine dinucleotide phosphate (NADPH)[506]; (2) purine nucleoside phosphorylase and xanthine oxidase, with measurement of hydrogen peroxide (H_2O_2) with peroxidase and a chromogenic substrate[3]; and (3) sucrose phosphorylase, phosphoglucomutase, and glucose-6-phosphate dehydrogenase, with measurement of the formation of the reduced form of nicotinamide-adenine dinucleotide (NADH).[556]

Specimen Requirements

Serum and heparinized plasma are the preferred specimens for the measurement of phosphate. Concentrations of inorganic phosphate are about 0.2 to 0.3 mg/dL (0.06 to 0.10 mmol/L) lower in heparinized plasma than in serum.[321] Anticoagulants such as citrate, oxalate, and EDTA interfere with formation of the phosphomolybdate complex.

Inorganic phosphate in whole blood specimens may either decrease or increase with time, depending on the type of specimen, the storage temperature, and the duration of storage.[318] Phosphate concentrations in plasma or serum are increased by prolonged storage with cells at room temperature or 37 °C. Hemolyzed specimens are unacceptable because erythrocytes contain high concentrations of organic phosphate esters, which can be hydrolyzed to inorganic phosphate during storage. Inorganic phosphate increases by 4 to 5 mg/dL (1.29 to 1.61 mmol/L) per day in hemolyzed specimens stored at 4 °C, more rapidly at room temperature or 37 °C. Glucose phosphate, creatine phosphate, and other organic phosphates may also be hydrolyzed by assay conditions, resulting in overestimation of inorganic phosphate concentrations.

Phosphate is considered to be stable in separated serum for days at 4 °C and for months when frozen, provided evaporation and lyophilization are prevented.

Interferences

Depending on the method used, positive or negative interference has been noted with hemolyzed, icteric, and lipemic specimens.[221,222] Mannitol,[156] fluoride, and monoclonal immunoglobulins[438] have also been reported to interfere. Glassware should be properly cleaned and rinsed because phosphate is a common component of many detergents.

Reference Intervals

Phosphate is often referred to as "phosphorus," a practice that is inaccurate and misleading because only phosphate, not elemental phosphorus, circulates in blood and is measured. This practice originated because results are reported as milligrams per deciliter of phosphorus, rather than phosphate. When results are reported in molar units (as in SI), the numerical results and reference intervals are the same for phosphorus and phosphate, but confusion occurs when results are reported in mg/dL.

In adults, the reference interval for serum phosphate is 2.5 to 4.5 mg of phosphorus/dL (0.81 to 1.45 mmol/L). In children, it is 4.0 to 7.0 mg phosphorus/dL (1.29 to 2.26 mmol/L).

Serum phosphate concentrations are about 50% higher in infants than in adults and decline throughout childhood,[227] a consequence of the ability of growth hormone to increase the renal phosphate threshold. Serum phosphate is unchanged in elderly women but decreases in elderly men.[171,522] During pregnancy, serum phosphate decreases.[216]

Because a diurnal variation[95,120,298,436] in serum phosphate has been reported, fasting morning specimens are recommended (Figure 49-8). Concentrations are higher in the afternoon and evening. Serum phosphate concentrations are influenced by dietary intake and meals and increased by exercise.

Urinary phosphate varies with age, muscle mass, renal function, PTH, the time of day, and other factors. Urinary excretion of phosphate varies widely with diet and is essentially equivalent to dietary intake. On a nonrestricted diet, the reference interval for urinary phosphate is 0.4 to 1.3 g/day (12.9 to 42.0 mmol/day).

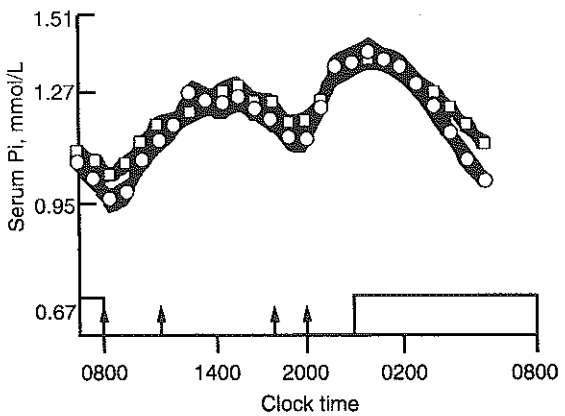

Figure 49-8 Diurnal variation of serum phosphate in men (○) and women (□). Meals and snacks are indicated by arrows; the bar indicates recumbent posture. *(From Calvo MS, Eastell R, Offord KP, Bergstralh EJ, Burritt MF. Circadian variation in ionized calcium and intact parathyroid hormone: evidence for gender differences in calcium homeostasis. J Clin Endocrinol Metab 1991;72:69-76, © The Endocrine Society.)*

Urine should be collected in 6 mol/L HCl, 20 to 30 mL for a 24-hour specimen, to avoid precipitation of phosphate complexes. Simultaneous measurement of phosphate and creatinine in serum and urine with fasting morning spot or 1- to 2-hour timed collections permits calculation of the renal phosphate threshold ($TmPO_4/GFR$). The clearance of phosphate divided by creatinine clearance can be plotted on a nomogram, and the $TmPO_4/GFR$ determined.[36,541] This index expresses phosphate reabsorption as a function of both serum phosphate concentration and GFR and is more useful than urinary phosphate excretion.

MAGNESIUM

Magnesium is the fourth most abundant cation in the body and the second most prevalent intracellular cation.[487,490] The total body magnesium content is approximately 25 g (1.03 mol), of which about 55% resides in the skeleton (see Table 49-1). One third of skeletal magnesium is exchangeable and is thought to serve as a reservoir for maintaining extracellular magnesium concentration. About 45% of magnesium is intracellular.

Biochemistry and Physiology

The concentration of magnesium in cells is approximately 1 to 3 mmol/L (2.4 to 7.3 mg/dL). In general, the higher the metabolic activity of a cell, the higher its magnesium content. Within the cell, most of the magnesium is bound to proteins and negatively charged molecules; 80% of cytosolic magnesium is bound to ATP, and MgATP is the substrate for numerous enzymes. The nucleus, mitochondria, and endoplasmic reticulum contain significant amounts of magnesium. Approximately 0.5% to 5.0% of the total cellular magnesium is free. Transport of magnesium across the cellular membrane is regulated by a specific magnesium transport system.

Extracellular magnesium accounts for about 1% of the total body magnesium content. About 55% of magnesium is free, 30% is associated with proteins (primarily albumin), and 15% is complexed with phosphate, citrate, and other anions (see Table 49-2).

Magnesium is a cofactor for more than 300 enzymes in the body.[487,490] It is required for enzyme substrate formation (for example, MgATP). In addition, magnesium is an allosteric activator of many enzyme systems. Examples of enzymes that require magnesium for action include adenylate cyclase, Na^+-K^+-adenosine triphosphate (ATPase), Ca^{2+}-ATPase, phosphofructokinase, and creatine kinase. The guanine nucleotide regulatory proteins Gs and Gi require magnesium for activity. Magnesium is important in oxidative phosphorylation, glycolysis, cell replication, nucleotide metabolism, and protein biosynthesis.

Reducing the serum magnesium concentration decreases the threshold of axonal stimulation and increases nerve conduction velocity. Magnesium also influences the release of neurotransmitter at the neuromuscular junction by competitively inhibiting the entry of calcium in the presynaptic nerve terminal. Reducing the serum magnesium concentration results in increased neuromuscular excitability.

Clinical Significance

Disorders of magnesium metabolism are separated into those causing hypomagnesemia/magnesium deficiency and hypermagnesemia.

Hypomagnesemia/Magnesium Deficiency

Hypomagnesemia is common in hospitals.[487,490] Ten percent of the patients admitted to city hospitals and as many as 65% of patients in intensive care units may be hypomagnesemic. Moderate or severe magnesium deficiency is usually due to losses of magnesium from the gastrointestinal (GI) tract or kidneys (Box 49-7).

GI, vomiting, and nasogastric suction may deplete body stores of magnesium as upper GI fluids contain approxi-

BOX 49-7 Differential Diagnosis of Magnesium Deficiency

- Gastrointestinal disorders
  - Prolonged nasogastric suction
  - Malabsorption syndromes
  - Extensive bowel resection
  - Acute and chronic diarrhea
  - Intestinal and biliary fistulas
  - Protein-calorie malnutrition
  - Acute hemorrhagic pancreatitis
  - Primary hypomagnesemia (neonatal)
- Renal loss
  - Chronic parenteral fluid therapy
  - Osmotic diuresis
    - Glucose (diabetes mellitus)
    - Mannitol
    - Urea
  - Hypercalcemia
  - Alcohol
  - Drugs
    - Diuretics (furosemide, ethacrynic acid)
    - Aminoglycosides
    - Cisplatin
    - Cyclosporine
    - Amphotericin B
    - Cardiac glycosides
    - Pentamidine
  - Metabolic acidosis (starvation, ketoacidosis, alcoholism)
  - Renal diseases
    - Chronic pyelonephritis, interstitial nephritis, and glomerulonephritis
    - Diuretic phase of acute tubular necrosis
    - Postobstructive nephropathy
    - Renal tubular acidosis
    - Post–renal transplantation
  - Primary hypomagnesemia
  - Phosphate depletion

mately 0.5 mmol/L of magnesium. More commonly, magnesium deficiency is associated with losses from the lower intestine. Diarrhea may result in marked losses of magnesium; therefore, acute diarrheal states, regional enteritis, and ulcerative colitis are frequently complicated by magnesium deficiency. Because magnesium is most efficiently absorbed from the distal small bowel, malabsorption and bypass surgery for obesity are also associated with magnesium malabsorption.

Excessive urinary losses of magnesium from the kidneys are important causes of magnesium deficiency. Clinically important causes include alcohol, diabetes mellitus (osmotic diuresis), loop diuretics (furosemide), and aminoglycoside antibiotics. Increased sodium excretion (parenteral fluid therapy) and increased calcium excretion (hypercalcemic states) also result in renal magnesium wasting.

Because magnesium deficiency is usually secondary to another disease process or to a therapeutic agent, the features of the primary disease process may complicate or mask magnesium deficiency. Neuromuscular hyperexcitability with tetany and seizures may be present. These symptoms and signs may also be due to hypocalcemia, and magnesium deficiency is a common cause of hypocalcemia. Magnesium deficiency impairs PTH secretion and causes resistance to PTH in the kidneys and bone.

One of the more serious complications of magnesium deficiency is cardiac arrhythmias. Premature atrial complexes, atrial tachycardia and fibrillation, ventricular premature complexes, ventricular tachycardia, and ventricular fibrillation may be associated with magnesium deficiency. These effects may be partly caused by the hypokalemia, renal wasting, and intracellular depletion of potassium caused by hypomagnesemia.

Although extracellular magnesium accounts for only about 1% of total body magnesium, and plasma magnesium concentrations correlate poorly with total body magnesium, determination of serum magnesium is the most widely used test to assess magnesium deficiency. Hypomagnesemia is often transient and not an indication of magnesium deficiency. Conversely, intracellular magnesium depletion and magnesium deficiency may exist despite a normal serum magnesium concentration. Consequently, hypocalcemia, hypokalemia, neuromuscular hyperirritability, and cardiac arrhythmias should alert one to the possible presence of magnesium deficiency. Other tests less commonly used include the magnesium tolerance test and measurements of intracellular magnesium (e.g., in red blood cell, lymphocyte, or skeletal muscle).[487]

Acute symptomatic magnesium deficiency is usually treated with parenteral magnesium; mild depletion may be treated with oral magnesium.

Hypermagnesemia

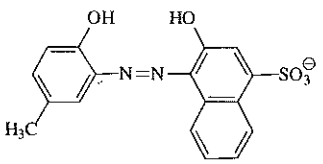
Magnesium intoxication is not a frequently encountered clinical problem, although mild to moderate elevation in the serum magnesium concentration may be noted in as many as 12% of hospital patients.[385,490] Symptomatic hypermagnesemia is almost always casued by excessive intake, resulting from the administration of antacids, enemas, and parenteral fluids containing magnesium (Box 49-8). The majority of these patients have concomitant renal failure, thereby limiting the ability of the kidneys to excrete excess magnesium. Magnesium is a standard therapy for pregnancy-induced hypertension (preeclampsia and eclampsia) and may cause magnesium intoxication in mothers and their neonates.

Depression of the neuromuscular system is the most common manifestation of magnesium intoxication. Deep tendon reflexes disappear at a serum magnesium above 5 to 9 mg/dL [2.06 to 3.70 mmol/L], whereas depressed respiration and apnea, caused by voluntary muscle paralysis, may occur at serum magnesium concentrations greater than 10 to 12 mg/dL (4.11 to 4.94 mmol/L). Higher concentrations may result in cardiac arrest. Somnolence, hypotension, nausea, vomiting, and cutaneous flushing may also be seen. Hypermagnesemia induces a decrease in the serum concentration of calcium, presumably because of the inhibition of both PTH secretion and end-organ action of PTH by magnesium.

The possibility of magnesium intoxication should be anticipated in patients receiving magnesium, especially those with renal failure. Replacement therapy should be discontinued in patients with mildly to moderately increased serum magnesium. Higher serum concentrations are used in treatment of preeclampsia and eclampsia. Since calcium acutely antagonizes the toxic effects of magnesium, patients with severe magnesium intoxication may be treated with intravenous calcium. If necessary, peritoneal dialysis or hemodialysis against a low-dialysis magnesium bath effectively lowers the serum magnesium concentration.

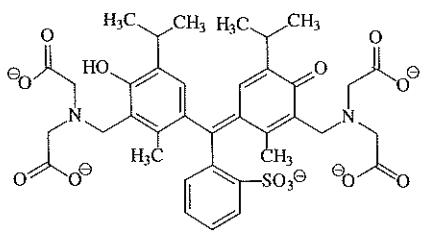
BOX 49-8 Causes of Hypermagnesemia

- Excessive intake
  - Orally (usually in the presence of chronic renal failure)
    - Antacids
    - Cathartic
  - Rectally
    - Purgation
  - Parenterally
    - Treatment of pregnancy-induced hypertension
    - Treatment of magnesium deficiency
- Renal failure
  - Chronic (usually with administration of magnesium)
    - Antacid
    - Cathartic
    - Enema
    - Infusion
    - Dialysis
  - Acute
    - Rhabdomyolysis
- Familial hypocalciuric hypercalcemia
- Lithium ingestion



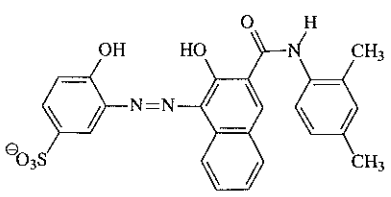
Measurement of Total Magnesium

Serum magnesium has been measured by various techniques including fluorometry, flame emission spectroscopy, and atomic absorption spectrometry (AAS).[252,590,606] Today, photometric methods are most commonly used by clinical laboratories, although AAS,[363] considered the reference method, is also used by a few laboratories.



Photometric Methods

Several metallochromic indicators or dyes change color on selectively binding magnesium and have been used to measure it in biological samples.[252,590,606] According to the College of American Pathologists Comprehensive Chemistry Survey for 2004, calmagite and methylthymol blue were each used by 26% of laboratories for magnesium determinations, followed by a formazan dye (23%), magon/xylidyl blue (15%), chlorophosphonazo III (7%), and arsenazol (2%).



Calmagite (1-[1-hydroxy-4-methyl-2-phenylazo]-2-naphthol-4-sulfonic acid) (Figure 49-9), a metallochromic indicator, forms a colored complex with magnesium in alkaline solution, which is measured at 530 to 550 nm.[1,335,503,590] A specific calcium-chelating agent, EGTA (see Figure 49-3), is added to reduce interference by calcium. Reagents may include potassium cyanide (to prevent formation of heavy metal complexes) and polyvinylpyrrolidone and surfactants to reduce interference from protein and lipemia.

Calmagite

Methylthymol blue

Xylidyl blue (Magon)

Figure 49-9 Metallochromic indicators for magnesium.

Methylthymol blue (see Figure 49-9) forms a blue complex with magnesium, which is measured around 600 nm.[606] EGTA is added to reduce interference by calcium.

A formazan dye (1,5-bis[3,5-dichloro-2-hydroxyphenyl]-3-formazan carbonitrile) forms a complex with magnesium at alkaline pH, which has been measured at 630 nm by thin-film reflectance photometry.[569] *N,N'*-[1,2-ethanediylbis[oxy-2,1-phenylene]bis(N-carboxymethyl)] glycine is used to chelate calcium. This thin-film reflectance method shows relatively little interference from icteric, lipemic, and hemolyzed specimens. Elevated calcium concentrations cause a measurable but small overestimation.

Magon, or xylidyl blue (1-azo-2-hydroxy-3-[2,4-dimethylcarboxanilido]-naphthalene-1'-[2-hydroxybenzene]) (see Figure 49-9), binds magnesium in alkaline solution, causing a spectral shift and forming a red complex.[28,83,131,357] The absorbance has most often been measured around 600 nm. Calcium and protein interferences are reduced by EGTA and dimethyl sulfoxide, respectively.

Atomic Absorption Spectrometry

As with calcium, AAS methods provide greater accuracy and precision for magnesium measurements than do photometric methods; however, they are not frequently used for routine determination of magnesium by clinical laboratories. AAS is used as a reference method for magnesium.

Magnesium is determined by AAS after diluting the specimen 1:50 with a solution of lanthanum-HCl to eliminate interference from anions, including phosphate and protein and metal oxides.[363,606] The dilution also reduces viscosity, ensuring that the aspiration rates for aqueous calibrators and specimens are comparable. The specimen is aspirated into an air-acetylene flame, in which the ground state magnesium ions absorb light from a magnesium hollow cathode lamp (285.2 nm). Absorption at 285.2 nm is directly proportional to the number of ground state magnesium atoms in the flame. Electrothermal atomic absorption methods have also been described for serum, urine, and other fluids.

Other Methods

Flame emission, fluorometric, and enzymatic methods have also been used to measure magnesium. Flame emission spectroscopy is not a good method for magnesium because of its poor emission at low temperature and interference by large concentrations of sodium, potassium, and phosphate. A number of fluorometric methods have used calcein or 8-hydroxyquinoline. Enzymatic methods[549,578] have been developed with hexokinase or other enzymes that use Mg^{2+}-ATP as a substrate. The rate of this reaction is dependent on the concentration of magnesium in the sample. Coupling hexokinase to glucose-6-phosphate dehydrogenase allows the reaction to be monitored at 340 nm with the formation of NADPH. A simple one-step reaction using stabilized isocitrate dehydrogenase has been reported.[197,545] This enzyme is activated by magnesium and produces NADPH.

Measurement of Free (Ionized) Magnesium

Instruments for the measurement of free magnesium in whole blood, plasma, or serum are available commercially.* These instruments use ISEs with neutral carrier ionophores, including ETH 5220, ETH 7025, or a proprietary ionophore. Current ionophores or electrodes have insufficient selectivity for magnesium over calcium. Free calcium is simultaneously determined and used chemometrically with the signal from the magnesium electrode to calculate free magnesium concentrations.

Comparisons of instruments for free magnesium determinations have been reported.† Electrodes are warranted by the manufacturer for as little as a couple days to several months. Differences in measured free magnesium were apparent between analyzers, mainly because of interference from free calcium. Further improvements in ISEs and instruments for free magnesium would improve performance and increase the availability of these determinations.

Decreased total magnesium is a common finding in hospital patients.[487,490] Magnesium salts are frequently administered to patients for antiarrhythmic, vasomotor, and neuronal actions and to patients with preeclampsia, myocardial infarctions, and ischemic heart disease. Monitoring of free magnesium concentrations has been suggested,[524] as both low and high concentrations can be life threatening.

Discordance between total and free magnesium measurements has been reported in selected patient populations, including those with cardiovascular disorders, diabetes mellitus, alcoholism, migraine headaches, asthma, renal transplants, head trauma, and in pregnant women.[10,615] Interferences, such as that from thiocyanate, in measurement of free magnesium may explain some of these discrepencies. Free magnesium determinations may be helpful in others of these disorders and in critically ill patients and during cardiopulmonary bypass, preeclampsia, neonatal distress, and therapy with a number of drugs.[310,311,501,502,615]

Specimen Requirements

Serum and heparinized plasma are the preferred specimens for measuring magnesium. Zinc heparin, lithium-zinc heparin, and some of the newer heparins developed for free calcium determinations should be avoided because they significantly increase magnesium.[574,603] Other anticoagulants, such as citrate, oxalate, and EDTA, are not acceptable because they form complexes with magnesium. Storage of serum for days at 4 °C and for months frozen does not affect measured concentrations of total magnesium provided evaporation of the specimen is prevented.

Serum or plasma must be separated from the clot or red blood cells as soon as possible to prevent an increase in serum magnesium because of cell leakage. Because erythrocytes contain higher concentrations of magnesium than serum or plasma, hemolyzed specimens are unacceptable. Interference by icterus or lipemia depends on the method and can be decreased by use of bichromatic analysis or blanking with EDTA.[221,222,335,374] Lipemic specimens should be ultracentrifuged.

Urine specimens should be collected in acid (e.g., HCl, 20 to 30 mL of 6 mol/L for a 24-hour specimen) to prevent precipitation of magnesium complexes. As with calcium, if acid must be added after collection, the entire specimen must be acidified, warmed, and mixed thoroughly before a sample is removed for analysis. Collection of the specimen in acid to prevent precipitation is recommended.

Factors that alter free calcium concentration by altering the distribution of calcium between free, protein-bound, and complexed pools can also alter free magnesium concentration.[98,524] Therefore specimens should be handled anaerobically to prevent loss of CO_2 and analyzed without delay to prevent changes in pH because of metabolism. As with free calcium, high concentrations of heparin should be avoided. Certain silicones or other tube additives, thiocyanate (smokers and diet), and zinc heparin interfere with free magnesium determinations.[98,457,468,524]

Reference Intervals for Total and Free Magnesium

For adults, the reference interval for serum magnesium is 1.7 to 2.4 mg/dL (0.66 to 1.07 mmol/L).[139,422] Magnesium concentrations in erythrocytes are approximately three times those of serum. Conversion factors for the units used to express magnesium concentration are given below:

$$\text{mmol/L} = \text{mEq/L} \times 0.5 = \text{mg/dL} \times 0.41$$
$$\text{mEq/L} = \text{mmol/L} \times 2 = \text{mg/dL} \times 0.82$$
$$\text{mg/dL} = \text{mEq/L} \times 1.22 = \text{mmol/L} \times 2.43$$

The reference interval for free magnesium is instrument-dependent; a typical range for the Nova Biomedical CRT is listed below:

0.45 to 0.60 mmol/L

HORMONES REGULATING MINERAL METABOLISM

PTH and 1,25-dihydroxyvitamin D are the primary hormones regulating bone and mineral metabolism. Calcitonin has pharmacological actions, but a physiological role has not been established in adults. PTHrP is the principal mediator of humoral hypercalcemia of malignancy.

Parathyroid Hormone

PTH is synthesized and secreted by the parathyroid glands; usually two superior and two inferior, located bilaterally on or near the thyroid gland capsule.[612] The glands are composed of chief and oxyphil cells; the chief cells synthesize, store, and secrete PTH.

*References 11-13, 176, 361, 483, 497, 585.
†References 9, 10, 98, 102, 273, 274, 456.

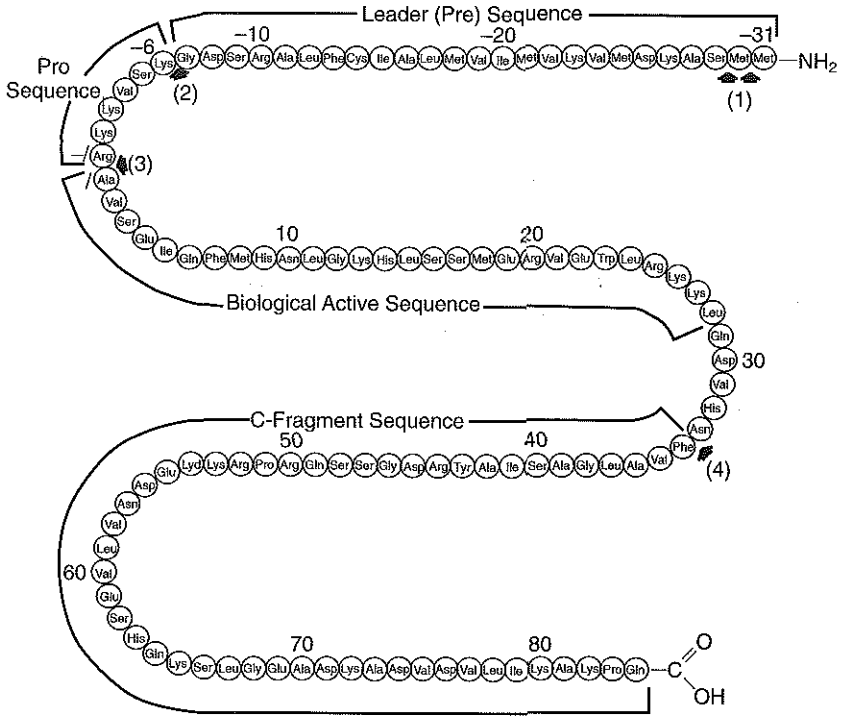


Figure 49-10 Amino acid sequence of preproparathyroid hormone. Arrows indicate the sites of cleavage by proteases to remove the N-terminal methionines (*1*), the leader (pre) sequence (*2*), and the pro sequence (*3*), producing intact PTH (1-84). Cleavage at position 4 produces inactive carboxyl (C)-terminal fragments. *(From Habener JF, Rosenblatt M, Potts JT Jr. Parathyroid hormone: Biochemical aspects of biosynthesis, secretion, action, and metabolism. Physiol Rev 1984;64:985-1053.)*

Biochemistry and Physiology

The concentration of PTH in plasma is determined by its synthesis and secretion by the parathyroids and its metabolism and clearance by the liver and kidneys. PTH acts directly on bone and kidney, and indirectly on intestine to regulate the concentration of calcium and phosphate in plasma.

Synthesis and Secretion

PTH is synthesized as a precursor, pre-pro-PTH, of 115 amino acids (Figure 49-10).[437] The amino(N)-terminal hydrophobic "pre" or leader sequence (25 amino acids) is involved in transporting PTH across the endoplasmic reticulum membrane into the cisternae. Both the "pre" and N-terminal "pro" (6 amino acids) are enzymatically cleaved during intracellular processing and before packaging in the Golgi apparatus. After processing, intact PTH (84 amino acids, molecular weight of 9425) is secreted, stored, or degraded intracellularly. Unlike proinsulin, proPTH does not appear to be secreted or to circulate in measurable concentrations.

Classical biological activity resides in the first third or N-terminal region of intact PTH. Synthetic PTH(1-34) is at least as potent as intact PTH(1-84) at interacting with the PTH/PTHrP receptor (type 1 PTH receptor) and stimulating calcemic, phosphaturic, and other biological responses in kidney and bone. Oxidation of the methionine residues at position 8 or 18 results in loss of biological activity. PTH contains a large number of basic amino acids. The middle portion of the molecule is quite immunogenic because of its hydrophobicity and species specificity.

The concentration of free calcium in blood or extracellular fluid is the primary acute physiological regulator of PTH synthesis, metabolism, and secretion.[76,435,437] Free calcium is sensed by a calcium-sensing receptor in the plasma membrane of parathyroid cells; this receptor activates intracellular events leading to release of free calcium from intracellular stores and the opening of plasma membrane calcium channels.[104] An increase in extracellular free calcium inhibits PTH synthesis and secretion and increases PTH metabolism, whereas a decrease has the opposite effect. An inverse sigmoidal relationship exists between PTH secretion and free calcium (Figure 49-11). Maximal secretion and suppression are attained with mild hypocalcemia and mild hypercalcemia, respectively. The midpoint of this relationship, or set-point, is the calcium concentration at which PTH secretion is half maximal. Set-points appear to vary somewhat from individual to individual and may be altered by physiological or pathological processes.

$1,25(OH)_2D$, phosphate, and magnesium also influence the synthesis and secretion of PTH.[76,435,437] $1,25(OH)_2D$ interacts with vitamin D receptors in the parathyroid glands to chronically suppress PTH synthesis by suppressing PTH gene transcription and therefore secretion. Hyperphosphatemia and hypophosphatemia increase and decrease PTH synthesis and secretion, respectively. Magnesium probably does not play an important role in PTH secretion except at the extremes of magnesium concentration. Chronic severe hypomagnesemia, such as that occurring in alcoholism, has been associated with impaired PTH secretion, whereas acute hypomagnesemia may stimulate secretion. Hypermagne-

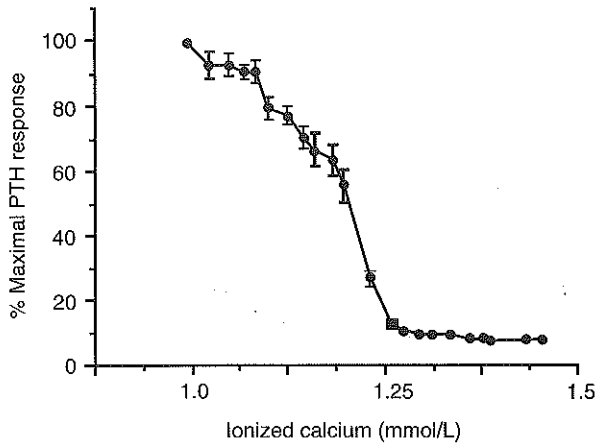

Figure 49-11 Regulation of intact PTH secretion by calcium in normal humans. Calcium and EDTA were infused to demonstrate the sigmoidal relationship between PTH secretion and free calcium. *(From Brown EM. Extracellular Ca^{2+} sensing, regulation of parathyroid cell function, and role of Ca^{2+} and other ions as extracellular (first) messengers. Physiol Rev 1991;71:371-411.)*

semia suppresses PTH secretion via the calcium-sensing receptor, although not as effectively as calcium.

Biological Actions

PTH influences both calcium and phosphate homeostasis directly through its actions on both bone and kidney and indirectly on the intestine through $1,25(OH)_2D$.[72,401,437,541] PTH exerts its actions by interacting with PTH/PTHrP receptors located in the plasma membrane of target cells. This interaction initiates a cascade of intracellular events, including the generation of cyclic adenosine monophosphate (cAMP), activation of kinases, phosphorylation of proteins, increased entry of calcium and intracellular calcium, stimulated phospholipase C activity with generation of diacylglycerol and phosphoinositide-activated enzyme and transport systems, and secretion of lysosomal enzymes.[437,541]

In the kidneys, PTH (1) induces 25-hydroxyvitamin D-1α-hydroxylase, increasing the production of $1,25(OH)_2D$, which stimulates intestinal absorption of both calcium and phosphate, (2) increases calcium reabsorption in the distal convoluted tubule of the nephron, (3) decreases reabsorption of phosphate by the proximal tubule, and (4) inhibits Na^+-H^+ antiporter activity, which favors a mild hyperchloremic metabolic acidosis in hyperparathyroid states.

The effects of PTH on bone are complex, as evidenced by its stimulation of bone resorption or bone formation, depending on the concentration of PTH and the duration of exposure. Chronic exposure to high concentrations of PTH leads to increased bone resorption. PTH acts directly by altering the activity or numbers of osteoblasts and indirectly on osteoclasts. Bone resorption, a prompt effect, is important for the maintenance of calcium homeostasis, whereas delayed effects are important for extreme systemic needs and skeletal homeostasis.

Integration of the direct effects of PTH on bone and kidney, and the indirect effects on intestine through $1,25(OH)_2D$, result in alterations in calcium and phosphate concentrations in serum and urine. In serum, total and free calcium are increased, but the concentration of phosphate is decreased. In urine, inorganic phosphate and cAMP concentrations are increased. Urinary calcium is usually increased because the larger filtered load of calcium (deriving from bone resorption and intestinal calcium absorption) overrides increased tubular reabsorption of calcium. In the absence of disease, the increase in serum calcium reduces PTH secretion through a negative-feedback loop, maintaining homeostasis.

Metabolism and Circulating Heterogeneity

PTH circulates as biologically active intact hormone and as carboxyl (C)-terminal fragments containing the midregion and C-terminal amino acids, but lacking the biologically active amino(N)-terminal region. Its heterogeneity is a consequence of (1) the secretion of both intact hormone and C-terminal fragments by the parathyroids, (2) peripheral metabolism of intact hormone by liver and kidney to C-terminal fragments, and (3) renal clearance of intact hormone and C-terminal fragments (Figure 49-12).[127,130,437] In the parathyroids, secretion of intact PTH is increased by hypocalcemia and greatly reduced or absent in hypercalcemia, whereas secretion of C-terminal fragments persists in hypercalcemia.[127,173,437] Biologically active intact PTH is rapidly cleared from plasma (half-life < 5 minutes) by metabolism to C-terminal fragments by the liver and kidneys and clearance of intact PTH by the kidneys.[437,509] Peripheral metabolism appears to inactivate intact hormone without releasing measurable concentrations of biologically active N-terminal fragments.[73,437]

Circulating immunoreactive PTH is composed primarily of "inactive" C-terminal fragments and secondarily of intact hormone (see N-terminal-Truncated-Fragments and Second Generation Intact PTH Methods for a discussion of N-terminal-truncated fragments measured by first generation intact PTH immunoassays). Although the exact length of circulating C-terminal fragments is uncertain, fragments consisting of the middle and carboxyl regions of the molecule (e.g., amino acids 34-84, 36-84) have been most frequently reported. These fragments are devoid of the N-terminal region and classical PTH biological activity and were considered to be inactive degradation products. However, recent reports have identified C-terminal PTH receptors in bone cells and have suggested that these fragments may affect the maturation and biological activity of these cells. C-terminal fragments are cleared by glomerular filtration and normally have a half-life of less than 1 hour. Their half-life and circulating concentration are increased significantly in individuals with impaired renal function. Generally, 5% to 25% of the total immunoreactive PTH is

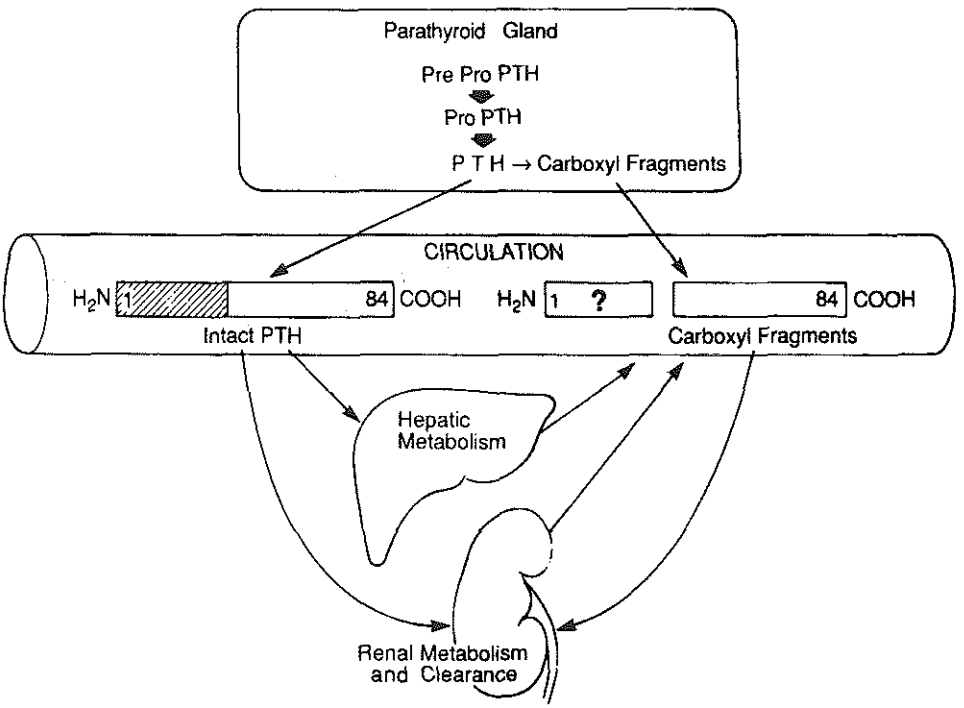

Figure 49-12 Secretion, metabolism, clearance, and circulating forms of PTH. Both intact PTH and inactive fragments containing the middle and carboxyl (C)-terminal amino acids are secreted by the parathyroid glands. These inactive fragments are also produced by peripheral metabolism of intact PTH by the liver and kidneys. Carboxyl fragments are cleared by the kidneys by glomerular filtration. The half-life and concentration of intact hormone are small compared with those of inactive fragments. *(From Endres DB, Villanueva R, Sharp CF Jr, Singer FR. Measurement of parathyroid hormone. Endocrinol Metab Clin North Am 1989;18:611-29.)*

intact hormone, and 75% to 95% is C-terminal fragments.[172,437,509] The relative concentrations of intact hormone and fragments vary with physiology and pathology.

Clinical Significance

Determination of PTH is useful in the differential diagnosis of both hypercalcemia and hypocalcemia for assessing parathyroid function in renal failure and for evaluating parathyroid function in bone and mineral disorders (see Calcium, Clinical Significance, Hypocalcemia, and Hypercalcemia; Metabolic Bone Diseases; and Interpretation of PTH Results).

Measurement of PTH

Noncompetitive immunoassays are now widely used for the measurement of intact PTH.[167,411] The low concentration of intact hormone and high concentrations of C-terminal fragments presented too great a challenge for competitive immunoassays.[172,509] Competitive immunoassays, primarily radioimmunoassays (RIAs), including those recognizing the midregion, C-terminal, N-terminal, and other sequences (Figure 49-13), have largely been discontinued because of their limited specificity and/or sensitivity. Midregion and C-terminal methods: (1) measure primarily C-terminal fragments, which are present in much higher concentrations than is biologically active intact hormone, the species regulated by free calcium; (2) often provide a poor indication of parathyroid function, because the measured concentration is dependent on peripheral metabolism and glomerular filtration of the fragments[437]; (3) are difficult to interpret in patients with impaired renal function (PTH can be falsely elevated, up to 30 times the upper limit of normal, in dialysis patients without secondary hyperparathyroidism)[18]; and (4) are not suppressed in nonparathyroid hypercalcemia and are often falsely modestly elevated.[173] N-terminal PTH RIAs were an attempt to overcome the limitations of assays measuring C-terminal fragments. These competitive immunoassays lacked the sensitivity required to measure intact PTH in patients with normal or modestly elevated concentrations.

Fortunately the following advances permitted the development of noncompetitive methods for intact PTH: (1) the determination of the amino acid sequence of human (h)PTH; (2) increased understanding of the secretion, metabolism, clearance, and circulating forms of PTH; and (3) the synthesis of hPTH, fragments of hPTH, and analogues of fragments for use as immunogens, tracers, and calibrators, for characterization of antiserum and antibody specificity, and for affinity purification of antibodies.

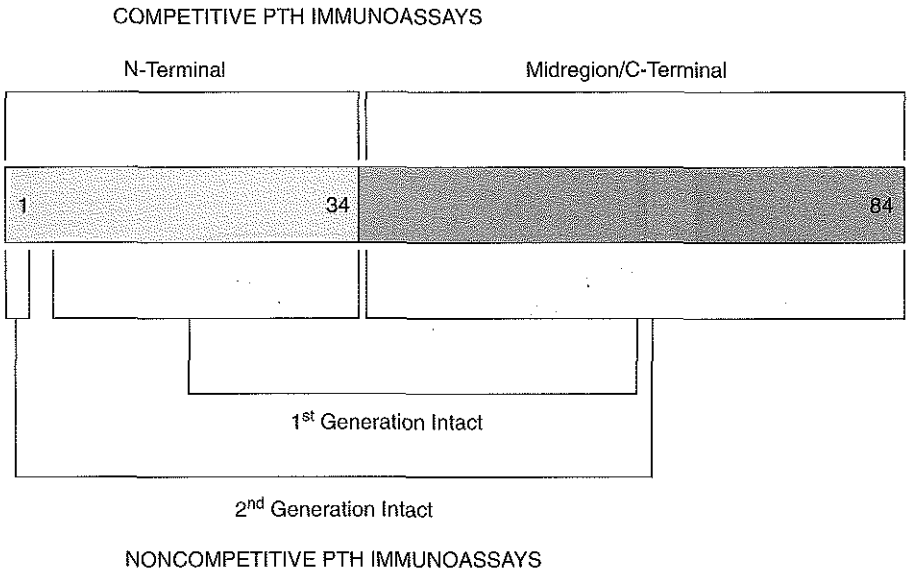

Figure 49-13 Schematic representation of PTH immunoassays including first and second generation noncompetitive intact immunoassays and midregion/C-terminal and N-terminal competitive methods. The approximate location of the peptide regions recognized by the antibodies of the four classes of methods is indicated. *(Modified from Jüppner H, Potts JT Jr. Immunoassays for the detection of parathyroid hormone. J Bone Miner Res 2002;17:N81-86.)*

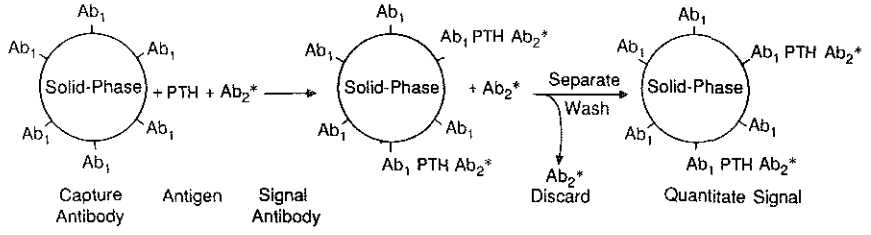

Figure 49-14 Noncompetitive immunoassay for PTH. PTH is reacted with immobilized capture antibody (Ab_1) against one antigenic determinant and a labeled signal antibody (Ab_2*) against a second antigenic determinant. PTH forms a bridge between the two antibodies, producing a "sandwich" or ternary complex. Both antibodies are added in excess, ensuring that all PTH reacts and is measured. Free signal antibody is separated, and the solid-phase antibody-PTH-labeled antibody complexes are quantified with an appropriate detection system. The signal increases with increasing concentrations of PTH. *(Modified from Endres DB, Villanueva R, Sharp CF Jr, Singer FR. Measurement of parathyroid hormone. Endocrinol Metab Clin North Am 1989;18:611-29.)*

Noncompetitive Methods for Intact PTH

Noncompetitive (also known as two-site, sandwich, labeled antibody, or immunometric methods) (see Chapter 9) require two antibodies capable of simultaneously binding PTH (Figure 49-14): (1) a capture antibody immobilized to a solid phase, and (2) a signal or reporter antibody labeled with a measurable substance or an enzyme changing the concentration (substrate or product) of a measurable substance. Unlike competitive immunoassays, with noncompetitive methods, both antibodies are added in excess, ensuring that all analyte is measured. After formation of the ternary complex or sandwich, excess labeled antibody is removed by washing before quantification of complexes. Noncompetitive immunoassays provide increased sensitivity, specificity, reproducibility, and convenience.[167,411]

For intact PTH, the capture antibody is most often directed against the carboxyl or middle region of the molecule (for example, amino acid sequences 39 to 84,[196,414] 44 to 68[78], 44 to 84, or 78 to 84[344]) and the signal antibody against the N-terminal amino acid sequence (1 to 34).[78,196,344,414] A few methods have reversed this, using capture antibodies against the N-terminal amino acid sequence (1 to 34,[55,62] 26 to 32, or 1 to 38[47]) and signal antibodies against the middle or C-terminal amino acid sequence (44 to 68,[62] 55 to 64, or 53 to 68).[47,55] With the latter, a higher concentration of signal antibody is required because of the high concentration of inactive fragments relative to intact hormone, potentially adversely impacting sensitivity by increasing the blank (signal in the absence of intact PTH). The specificity of these noncompetitive methods depends on the sequence specificity of the antibodies used. The methods described above do not measure classical C-terminal fragments lacking the N-terminal amino acid sequence (1-34).

Antibodies may be either monoclonal or polyclonal antibodies purified by affinity chromatography to produce sequence-specific antibodies. Affinity-purified polyclonal antibodies have been most widely used, particularly for the signal antibody, because of the difficulty of producing high-

affinity monoclonal antibodies against PTH, although some success has been reported.[62,77,343,344,413]

Capture antibodies have been noncovalently bound or covalently attached to a variety of solid phases, including polystyrene beads,[196,414] plastic tubes,[55,62] paramagnetic particles, microparticulate cellulose,[47,78] and sepharose.[344]

Signal antibodies have most often been radiolabeled (for *immunoradiometric* assays [IRMA]) with (^{125}I)[47,62,196,344,414] or labeled with a chemiluminescent (for *immunochemiluminometric* assays [ICMA]) compound, such as acridinium ester,[55,77] or an enzyme (enzyme-linked immunosorbent assay [ELISA] or enzyme immunoassay [EIA]), such as ALP, converting a substrate (1,2-dioxetane phosphate) to a chemiluminescent product.

As of 2004, the College of American Pathologists Interlaboratory Survey listed five manufacturers as providing first generation noncompetitive immunoassays for intact PTH. Most of these commercially available methods are on fully automated immunoassay analyzers using chemiluminescence detection including ALP with 1,2-dioxetane phosphate, acridinium ester, or electrochemiluminescence (ruthenium chelate). Signal antibody is less commonly radiolabeled with ^{125}I.

N-Terminal-Truncated PTH and Second Generation Intact PTH Methods

More recently, evidence has been presented for circulating N-terminal-truncated fragment(s) (also called non-[1-84]PTH and PTH[7-84]), containing all but a few of the N-terminal amino acids. The fragment(s) were identified by immunoassay with first generation noncompetitive methods for intact PTH after fractionation of extracts of plasma from hyperparathyroid patients and normal subjects by high-performance liquid chromatography (HPLC).[75,328] Although its exact length is unknown, the fragment(s) migrate before PTH(1-84) and just ahead of PTH(7-84). N-terminal-truncated PTH concentration accounts for averages of 20% and 50% of "intact" PTH in normal subjects and patients with chronic renal failure, respectively. Furthermore the relative concentration of N-terminal-truncated PTH increased with hypercalcemia and decreased with hypocalcemia. Like C-terminal fragments, N-terminal-truncated PTH originates from both secretion by the parathyroids and peripheral metabolism of intact hormone.[404]

First generation, noncompetitive methods for intact PTH cross-react with N-terminal-truncated fragment(s) overestimating the concentration of biologically active, intact PTH. Using synthetic PTH(7-84), cross-reactivity of 40% to 160% has been reported for first generation methods.[202,328] These findings have stimulated the development of a few second generation methods for intact PTH, using N-terminal antibodies that do not cross-react with synthetic PTH (7-84) (Figure 49-13). These second generation methods, which do not recognize N-terminal-truncated fragments, have been referred to as "bio-intact PTH, PTH(1-84)," "whole PTH," or "CAP" (cyclase-activating PTH). We prefer the term "second generation intact PTH" assays, but because of its convenience we will also use PTH(1-84) to distinguish these methods from first generation intact PTH methods that recognize both intact hormone and N-terminal-truncated PTH. This terminology avoids the implication that these immunoassays measure only biologically active hormone.

One method uses antibodies against PTH(1-4) and even requires the presence of the most N-terminal amino acid, as evidenced by its failure to recognize PTH(2-34).[202] As of 2004, three second generation methods from two manufacturers were listed on the College of American Pathologists Interlaboratory Survey.

Recent studies have suggested that N-terminal-truncated PTH may be biologically active. Synthetic PTH(7-84), used as the available representative of N-terminal-truncated PTH, decreased serum calcium; antagonized the calcemic, phosphatemic, and phosphaturic effects of intact PTH in thyroparathyroidectomized animals; and was bound by a C-terminal PTH receptor distinct from the PTH/PTHrP receptor.[405,531]

Since first generation methods for intact PTH measure N-terminal-truncated PTH, they overestimate the concentration of biologically intact hormone. The degree of overestimation will be method-dependent, but intact PTH is 50% higher on average than PTH(1-84) in patients with primary hyperparathyroidism or end-stage renal disease.[202]

The inability of first generation intact PTH methods to accurately measure biologically active intact hormone may explain why intact PTH is not a reliable indicator of bone turnover in dialysis patients.[356] PTH often fails to distinguish patients with low-, normal-, and high-turnover bone disease. Furthermore, treatment of patients to suppress intact PTH to normal or near normal frequently results in adynamic bone disease. Recently the PTH(1-84)/N-terminal-truncated fragment ratio has been proposed for evaluating bone turnover in renal osteodystrophy based on the ability of PTH(7-84) to antagonize the biological activity of intact PTH and preliminary experimental evidence for the predictive value of this ratio.[383] The ratio is calculated after measuring intact PTH (first generation) and PTH(1-84) (second generation) and calculating the N-terminal-truncated fragments by subtracting PTH(1-84) from intact PTH. Additional studies are required as subsequent studies were unable to substantiate the greater clinical utility of measuring both PTH(1-84) and intact PTH and calculating this ratio to assess bone turnover in renal osteodystrophy.[114,356,500A]

Even second generation intact PTH assays may not be absolutely specific for intact PTH as evidenced by a recent report demonstrating an amino-terminal form of PTH distinct from intact hormone and the N-truncated fragment. This form represented approximately 20% of the intact PTH measured with a second generation intact PTH method. The clinical implications of this form have not yet been established.[125A]

Specimen Requirements

Specimen requirements may depend on the specific method; however, serum or EDTA plasma is generally preferred. After

separation, serum or plasma should be frozen if the analysis is delayed. Lower concentrations of PTH are observed in serum incubated at room temperature for more than a few hours or after one to several days at 4 °C.[330,403,450,492,613] PTH has been reported to be more stable in EDTA plasma, a probable consequence of reduced proteolytic activity.

Reference Intervals

Reference intervals for PTH vary with the method. Typical reference intervals are:

Intact PTH (First Generation): 10 to 65 pg/mL
(1.1 to 6.8 pmol/L)
PTH(1-84) (Second Generation): 6 to 40 pg/mL
(0.6 to 4.2 pmol/L)

Interpretation of PTH concentrations should consider the patient's calcium concentration at the time of sampling.[329]

The upper limit of the reference interval for PTH may be inappropriately high because of the prevalence of vitamin D insufficiency and mild secondary hyperparathyroidism in the reference group. Significantly lower intervals have been established for these methods by excluding individuals with vitamin D insufficiency (see section on vitamin D, reference intervals).[534]

Intact PTH concentrations vary with age and are low or normal during pregnancy,[132,200,272,500] lower in fetuses and umbilical cord blood, and increased during the first few days of life,[424,484,499,500] in response to neonatal hypocalcemia. Concentrations in children and adolescents are reportedly similar, if not identical, to those in adults.[499] In healthy adults, circulating concentrations of intact PTH increase with age.[171,522]

Intact PTH is reported to be secreted in a pulsatile fashion with an overall circadian rhythm characterized by a nocturnal rise.[95,242,301,342] Measurement of PTH on more than one occasion should assist in preventing misinterpretation of parathyroid status because of episodic secretion.

Interpretation of PTH Results

PTH is the most important test for the differential diagnosis of hypercalcemia. Intact PTH is elevated in the majority of patients with primary hyperparathyroidism (see Figure 39-15)[78,168,173,414] and below normal or in the lower half of the reference interval in most patients with nonparathyroid hypercalcemia including hypercalcemia-associated malignancy.[78,173,414] In patients with stable hypercalcemia, PTH in the upper half of the reference interval is inappropriately high and suggestive of primary hyperparathyroidism. Whenever possible, PTH specimens should be obtained before therapy for hypercalcemia, because PTH

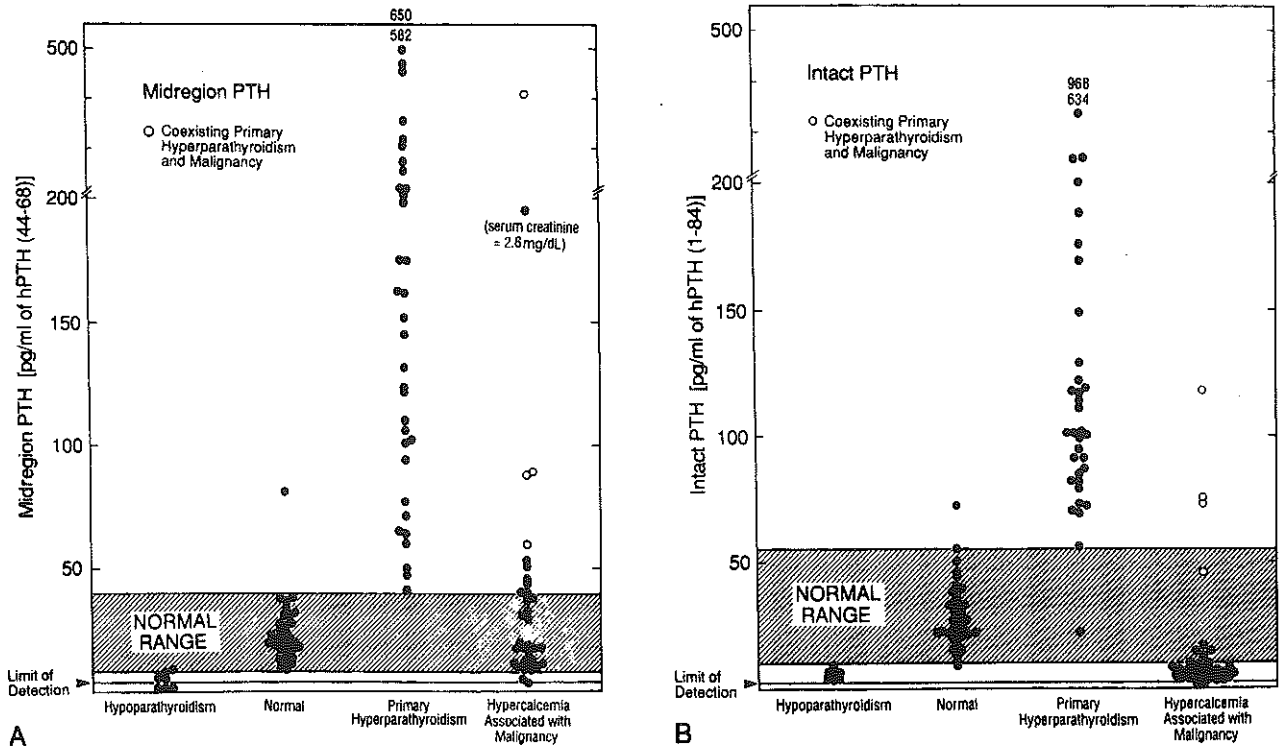

Figure 49-15 Midregion **(A)** and intact **(B)** PTH in normal subjects and patients with primary hyperparathyroidism, hypercalcemia associated with malignancy, and hypoparathyroidism. *(From Endres DB, Villanueva R, Sharp CF Jr, Singer FR. Measurement of parathyroid hormone. Endocrinol Metab Clin North Am 1989;18:611-29.)*

secretion may be stimulated by declining serum calcium.[193] Increased PTH in patients with hypercalcemia and malignancy suggests coexisting hyperparathyroidism and malignancy,[488] since ectopic PTH production appears to be extremely rare.[412] Hypercalcemia in malignancy is usually associated with bony metastases and/or production of PTHrP. PTHrP does not cross-react in any of the PTH immunoassays that have been evaluated. According to a recent study, PTH(1-84) is more sensitive in diagnosing primary hyperparathyroidism.[526] PTH(1-84) and intact PTH were elevated in 96% and 73% of 56 patients with primary hyperparathyroidism, respectively.

Intraoperative determination of intact PTH is useful for assessing the completeness of parathyroidectomy and facilitating minimally invasive parathyroid surgery, thereby improving cost-effectiveness and cosmetic outcomes.[100] PTH is measured just before the incision and again at 10 minutes after resection of the hyperfunctioning parathyroid tissue. A decline of 50% or more is usually considered indicative of the removal of all hyperfunctioning tissue. In contrast to patients with solitary parathyroid adenomas, interpretation of results in patients with multiglandular disease is more complicated. Preoperative or intraoperative PTH may also be useful for localization of hyperfunctioning parathyroid tissue by sampling multiple veins from the cervical and mediastinal regions. PTH(1-84) may decrease more rapidly and completely than intact PTH after removal of hyperfunctioning tissue.[617]

Subnormal or low normal PTH is observed in the majority of patients with hypoparathyroidism (see Figure 49-15); such concentrations are inappropriately low for patients with hypocalcemia.[62,78,173] The apparently detectable concentrations observed in many patients with hypoparathyroidism or nonparathyroid hypercalcemia may be a result of the imprecision of methods at low concentrations, a nonspecific serum (ligand-free matrix) effect, and/or measurement of N-terminal-truncated PTH.[130] More rigorous assessment of the limit of detection[407] of PTH immunoassays and use of PTH(1-84) methods may show that concentrations are undetectable in these patients.

In secondary hyperparathyroidism, PTH is increased before total or free calcium becomes abnormally low, a consequence of homeostatic mechanisms for maintenance of serum calcium. Consequently, PTH is more sensitive than calcium for identifying secondary hyperparathyroidism.

In patients with end-stage renal disease, measurement of PTH is helpful in assessing parathyroid function, in estimating bone turnover, and in improving management. Patients with high-turnover bone disease because of secondary hyperparathyroidism (advanced osteitis fibrosa) have the highest concentrations of PTH, whereas patients with low-turnover, adynamic bone disease, including osteomalacia, have the lowest concentrations (Figure 49-16).* Intermediate concentrations are seen in low-turnover adynamic (aplastic) disease and early osteitis fibrosa. Considerable overlap in intact PTH concentrations is apparent among the various forms of renal osteodystrophy. In dialysis patients, cut-points ("decision levels") of less than 100 or 150 pg/mL and greater than 250 to 300 pg/mL have been suggested for distinguishing patients with low-turnover and high-turnover bone disease, respectively. A reasonable therapeutic goal for intact PTH (first generation) concentrations is two to four times the upper limit of the reference interval to prevent parathyroid-suppressed, adynamic, and hyperparathyroid bone diseases.[340,595]

Parathyroid status is usually determined by measuring PTH on predialysis specimens, because various factors, including changes in serum calcium and the type of dialysis membrane, affect PTH secretion and clearance.[126,317] Comparison of predialysis and postdialysis specimens has been suggested for determining acute parathyroid responsiveness to alterations in serum calcium concentrations.[155,433,589]

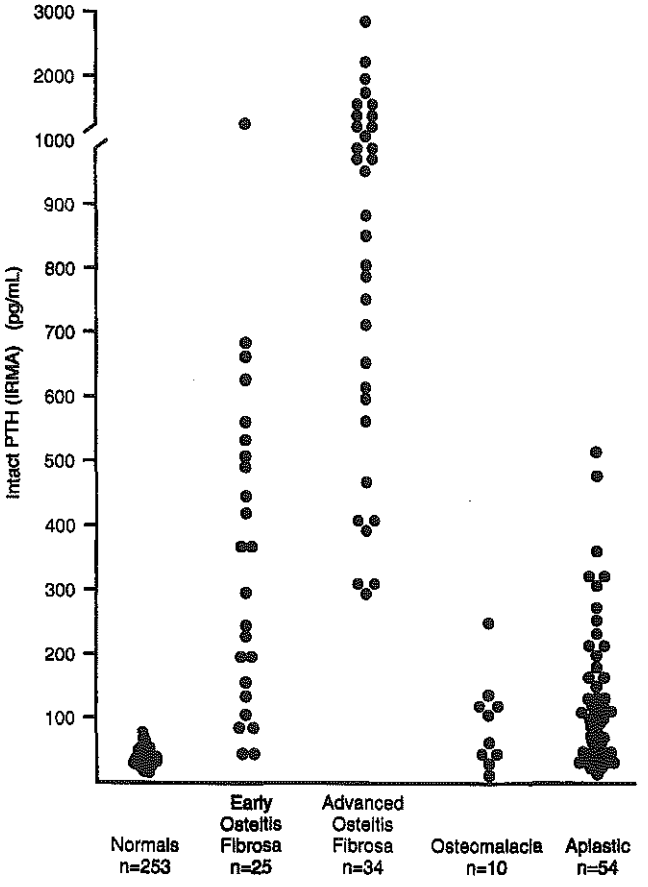

Figure 49-16 Intact PTH in assessing parathyroid function in end-stage renal disease. Dialysis patients were separated into those with early and advanced osteitis fibrosa, osteomalacia, and aplastic disease by quantitative histomorphometric analysis of undecalcified bone biopsies. *(From Segre GV, Sherrard DJ, Pandian MR, et al. Intact PTH (IRMA) II: New applications to issues in parathyroid hormone and mineral metabolism. San Juan Capistrano, Calif: Nichols Institute, 1989.)*

*References 18, 115, 340, 447, 510, 589, 595.

It is likely that PTH(1-84) will more accurately assess parathyroid status and bone turnover and guide therapy in patients with end-stage renal disease[356,383] (see N-Terminal Truncated PTH and Noncompetitive Methods for PTH(1-84). The therapeutic targets for intact PTH (two to four times the upper limit of normal) will need to be revised for PTH(1-84).

Noncompetitive immunoassays for intact PTH or PTH(1-84) must have high concentrations of the C-terminal antibody to avoid underestimating PTH in dialysis patients with secondary hyperparathyroidism who have high concentrations of C-terminal fragments. Absence of interference can be assessed by confirming that specimens from dialysis patients with the highest concentrations of PTH dilute in a parallel fashion.[46,154] Alternatively, recovery can be determined by adding a known amount of intact PTH to these specimens.

PTH concentrations may be altered in hyperthyroidism, in hypothyroidism, and with lithium carbonate treatment. PTH is decreased and inversely correlated with T3 concentrations in hyperthyroid patients. Serum PTH increases in patients who become hypothyroid after radioactive iodine treatment, and decreases with replacement therapy,[194,375,481] changes apparently mediated by serum calcium. Chronic lithium carbonate therapy has been reported to increase parathyroid gland size and circulating intact PTH.[354]

One remaining but uncommon use for PTH methods measuring C-terminal fragments is the analysis of fluid from suspected parathyroid cysts. Parathyroid cyst fluid appears to contain primarily inactive fragments of PTH, not intact hormone.[43]

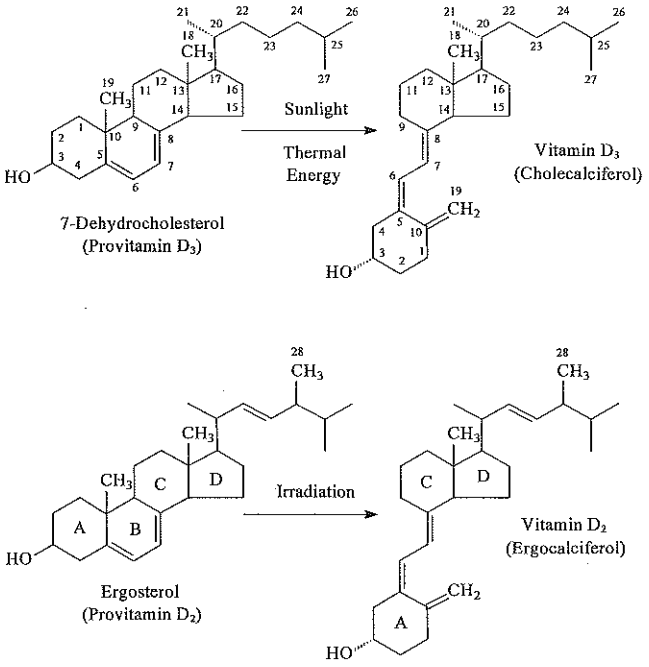

Figure 49-17 Structure of vitamin D_3 (cholecalciferol) and vitamin D_2 (ergocalciferol) and their precursors. 7-Cholecalciferol is produced in the skin from 7-dehydrocholesterol on exposure to sunlight. Ergocalciferol is produced commercially by irradiation of ergosterol. *(Modified from Holick MF, Adams JS. Vitamin D metabolism and biological function. In: Avioli LV, Krane SM, eds. Metabolic bone disease, 2nd ed. Philadelphia: WB Saunders, 1990:155-95.)*

Vitamin D and Its Metabolites

Vitamin D is produced endogenously by exposure of skin to sunlight, and is absorbed from foods containing or supplemented with vitamin D. Vitamin D is metabolized to its biologically active form, 1,25-dihydroxyvitamin D ($1,25[OH]_2D$), a hormone regulating calcium and phosphate metabolism. Deficiency of vitamin D results in impaired formation of bone, because of a mineralizing defect, producing rickets in children and osteomalacia in adults.

Biochemistry and Physiology

Vitamin D and its metabolites may be categorized as either cholecalciferols or ergocalciferols (Figure 49-17). Cholecalciferol (vitamin D_3) is the parent compound of the naturally occurring family and is produced in the skin from 7-dehydrocholesterol on exposure to the ultraviolet B portion of sunlight.[257,258] Latitude, season, aging, sunscreen use, and skin pigmentation influence production of vitamin D_3 by the skin. Vitamin D_2 (ergocalciferol), the parent compound of the other family, is manufactured by irradiation of ergosterol produced by yeasts. Vitamin D_2 differs from vitamin D_3 by the double bond between carbon 22 and carbon 23 and a methyl group on carbon 24. When vitamin D or its metabolites are written without a subscript, both families are included.

Only a few foods, primarily fish liver oils, fatty fish, egg yolks, and liver, naturally contain significant amounts of vitamin D.[257,258,410] Consequently, before foods were supplemented with vitamin D_2 or vitamin D_3, most vitamin D in the body was produced by synthesis in skin. In North America, a considerable fraction of vitamin D is acquired by ingestion of fortified foods (some cereals, bread products, and milk) or vitamin D supplements. The recommended daily allowance is 400 IU (10 μg).

Metabolism, Regulation, and Transport

Vitamin D_2 and vitamin D_3 are metabolized to 25-hydroxyvitamin D [25(OH)D] by vitamin D-25-hydroxylase, a cytochrome P450 enzyme, in liver (Figure 49-18).[146,257,258,458] The concentration of 25(OH)D in serum is approximately 10 to 65 ng/mL (25 to 162 nmol/L) (Table 49-4). The half-life of circulating 25(OH)D is 2 to 3 weeks. At physiological concentrations, 25(OH)D is biologically inactive.

25(OH) D_2 and $25(OH)D_3$ are metabolized to 1,25-dihydroxyvitamin D ($1,25[OH]_2D$), the biologically active hormone, by 25(OH)D-1α-hydroxylase, a cytochrome P450 enzyme, in kidney and placenta (see Figure 49-18). Normal circulating concentrations are approximately 15 to 60 pg/mL

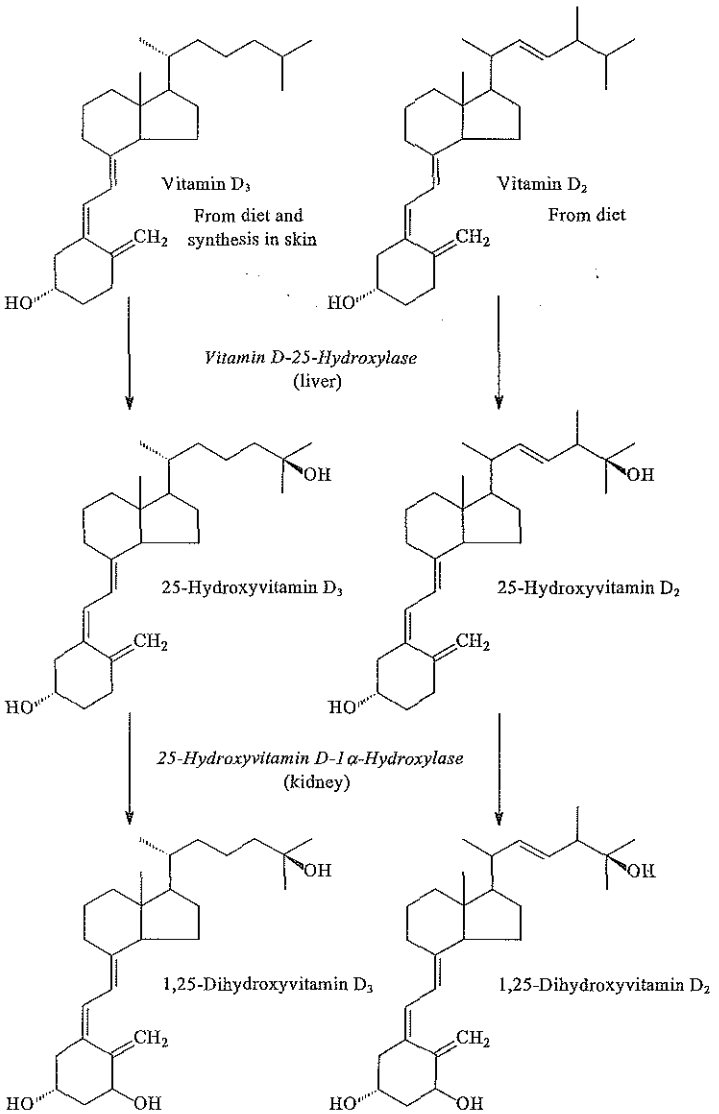

Figure 49-18 Metabolism of vitamin D. Vitamin D_2 and vitamin D_3 are enzymatically hydroxylated to 25-hydroxyvitamin D in the liver and 1,25-dihydroxyvitamin D by the kidneys. 1,25-Dihydroxyvitamin D_2 and 1,25-dihydroxyvitamin D_3 are the biologically active forms of vitamin D.

TABLE 49-4 Vitamin D and Its Metabolites in Plasma

Compound	Concentration	Free (%)	Half-Life
Vitamin D (ng/mL)	<0.2-20	—	1-2 days
(nmol/L)	<0.5-52		
25-Hydroxyvitamin D (ng/mL)	10-65	0.03	2-3 wk
(nmol/L)	25-162		
1,25-Dihydroxyvitamin D (pg/mL)	15-60	0.4	4-6 hr
(pmol/L)	36-144		

(36 to 144 pmol/L), about 1/1000 that of 25(OH)D (Table 49-4). The half-life of $1,25(OH)_2D$ is 4 to 6 hours.

Circulating concentrations of $1,25(OH)_2D$ are tightly regulated, primarily by PTH, phosphate, calcium, and $1,25(OH)_2D$.[146,147,257,258,458] PTH and hypophosphatemia increase the synthesis of $1,25(OH)_2D$ by increasing 25(OH)D-1α-hydroxylase, whereas hypocalcemia acts indirectly by stimulating the secretion of PTH. Hypercalcemia, hyperphosphatemia, and $1,25(OH)_2D$ reduce 25(OH)D-1α-hydroxylase and $1,25(OH)_2D$. $1,25(OH)_2D$ also induces 25(OH)D-24-hydroxylase, an enzyme producing 24,25-dihydroxyvitamin D ($24,25[OH]_2D$), the most prevalent

dihydroxylated vitamin D in serum. The activity of this enzyme may reduce the formation of biologically active $1,25(OH)_2D$.

Vitamin D, 25(OH)D, and $1,25(OH)_2D$ are bound in the circulation to vitamin D–binding protein (DBP), a specific, high-affinity transport protein also known as *group-specific component.*[119,257,258] In humans, DBP contains 458 amino acid residues and has a molecular weight of 51 335. DBP is synthesized by the liver and circulates in great excess (at about 400 mg/L), with fewer than 5% of the binding sites normally occupied. Vitamin D and its metabolites are bound with the following preference: $25(OH)D > 1,25(OH)_2D >>$ vitamin D. Only 0.03% of 25(OH)D and 0.4% of $1,25(OH)_2D$ are normally free in plasma (Table 49-4). DBP concentrations are increased in pregnancy and with estrogen therapy and are decreased in nephrotic syndrome.

Biological Actions of 1,25-Dihydroxyvitamin D

$1,25(OH)_2D$ helps to maintain calcium and phosphate in serum by its actions on intestine, bone, kidney, and the parathyroids. In the small intestine, $1,25(OH)_2D$ stimulates calcium absorption, primarily in the duodenum, and phosphate absorption by the jejunum and ileum.[146,147,257,258,458] At high concentrations, $1,25(OH)_2D$ increases bone resorption by inducing monocytic stem cells in bone marrow to differentiate into osteoclasts and by stimulating osteoblasts to produce cytokines and other factors influencing osteoclast activity. By stimulating osteoblasts, it also increases the circulating concentration of ALP and the noncollagenous bone protein osteocalcin (also called bone Gla protein, or BGP, because it contains γ-carboxyglutamic acid or Gla). In the kidneys, $1,25(OH)_2D$ inhibits its own synthesis and stimulates its metabolism. $1,25(OH)_2D$ also acts directly on the parathyroids to inhibit the synthesis and secretion of PTH. $1,25(OH)_2D$ exerts its actions by associating with a specific nuclear vitamin D receptor, analogous to the steroid receptors for androgens, estrogens, and corticosteroids (see Chapters 43 and 45).

Clinical Significance

Determination of vitamin D is useful in the differential diagnosis of hypocalcemia, hypercalcemia, or hypercalciuria and for evaluating vitamin D status in health and in bone and mineral disorders (see Calcium, Clinical Significance, Hypocalcemia, and Hypercalcemia; and Metabolic Bone Diseases). Only the measurements of 25(OH)D and $1,25(OH)_2D$ have proven clinical value.* Routine clinical determination of vitamin D, $24,25(OH)_2D$, or other metabolites is not indicated at this time.

Vitamin D nutritional status is determined best by the measurement of 25(OH)D (Box 49-9), rather than vitamin D because (1) 25(OH)D is the main circulating form of vitamin D (see Table 49-4), (2) 25(OH)D varies less, day-to-day, with exposure to sunlight and diet intake[256,258] because of its longer half-life, (3) and the measurement of 25(OH)D is relatively easy compared with the more technically complicated methods for vitamin D.[110,267,269] Groups at higher risk for developing nutritional vitamin D deficiency include breast-fed infants, strict vegetarians who abstain from eggs and milk, individuals of color, and the elderly.

BOX 49-9 Abnormal Circulating Levels of 25(OH)D

Decreased 25(OH)D
- Inadequate exposure to sunlight
- Inadequate dietary vitamin D
- Vitamin D malabsorption
- Severe hepatocellular disease
- Increased catabolism (e.g., drugs, such as anticonvulsants)
- Increased loss (nephrotic syndrome)

Increased 25(OH)D (hypercalcemia)
- Vitamin D or 25(OH)D intoxication

25(OH)D is useful in evaluating hypocalcemia, vitamin D status, bone disease, and other disorders of mineral metabolism. Circulating concentrations of 25(OH)D may be decreased by (1) reduced availability of vitamin D, (2) inadequate conversion of vitamin D to 25(OH)D, (3) accelerated metabolism of 25(OH)D, and (4) urinary loss of 25(OH)D with its transport protein. Reduced availability of vitamin D occurs with inadequate exposure to sunlight, dietary deficiency, malabsorption syndromes, or gastric or small bowel resection. Severe hepatocellular disease has been associated with inadequate conversion of vitamin D to 25(OH)D. Drugs such as phenytoin, phenobarbital, and rifampin induce drug-metabolizing enzymes that accelerate the metabolism of vitamin D and its metabolites. Serum 25(OH)D concentrations may be reduced in patients with nephrotic syndrome because of the urinary loss of DBP and 25(OH)D. Measurement of 25(OH)D has limited value in hypercalcemia. Its most common use in hypercalcemia is in confirming intoxication after ingestion of large amounts of vitamin D or 25(OH)D[587]; 25(OH)D concentration is typically greater than 100 ng/mL (250 nmol/L) in such patients.

Measurement of $1,25(OH)_2D$ is useful in detecting inadequate or excessive hormone production in the evaluation of hypercalcemia, hypercalciuria, hypocalcemia, and bone and mineral disorders (Box 49-10). Because activated macrophages convert 25(OH)D to $1,25(OH)_2D$, serum concentrations of $1,25(OH)_2D$ are often increased in sarcoidosis, tuberculosis, other granulomatous diseases. Rarely is lymphoma associated with increased concentrations of $1,25(OH)_2D$.[4] Concentrations of $1,25(OH)_2D$ are elevated in vitamin D–dependent rickets type II and in $1,25(OH)_2D$ intoxication, and may be elevated in primary hyperparathyroidism. Patients with primary hyperparathyroidism and

*References 22, 113, 257, 258, 458, 541.

BOX 49-10 Abnormal Levels of $1,25(OH)_2D$

Decreased $1,25(OH)_2D$
- Renal failure
- Hyperphosphatemia
- Hypomagnesemia
- Hypoparathyroidism
- Pseudohypoparathyroidism
- Vitamin D–dependent rickets, type I
- Hypercalcemia of malignancy

Increased $1,25(OH)_2D$
- Granulomatous diseases
- Primary hyperparathyroidism
- Lymphoma
- $1,25(OH)_2D$ intoxication
- Vitamin D–dependent rickets, type II

high concentrations of $1,25(OH)_2D$ appear to be more prone to developing hypercalciuria and renal stones. Reduced concentrations of $1,25(OH)_2D$ are observed in patients with renal failure, hypercalcemia of malignancy, hyperphosphatemia, hypoparathyroidism, pseudohypoparathyroidism, type I vitamin D–dependent rickets, hypomagnesemia, nephrotic syndrome, and severe hepatocellular disease. Measurement of $1,25(OH)_2D$ is not useful in confirming intoxication with vitamin D or 25(OH)D, because $1,25(OH)_2$ concentrations may be low, normal, or elevated.

Measurement of Vitamin D Metabolites

Specific and sensitive assays have been developed for vitamin D, 25(OH)D, and $1,25(OH)_2D$.[261] 25(OH)D and $1,25(OH)_2D$ assays should measure D_2 and D_3 metabolites equally (with "equimolar" reactivity), since both D_2 and D_3 are metabolized to produce biologically active $1,25(OH)_2D$. Separate measurement of the D_2 and D_3 forms does not necessarily distinguish dietary and endogenous sources of vitamin D, as food is supplemented with D_3 and D_2.[257]

Most assays for 25(OH)D and $1,25(OH)_2D$ contain two or three of the following steps: (1) deproteinization or extraction, (2) purification, and (3) quantification. Deproteinization or extraction frees the metabolites from DPB and may partially purify the metabolites. Purification steps, most often column chromatography, separate the various forms of vitamin D, lipid, and interfering substances. The method of quantification depends on the metabolite being measured.

Extraction and Deproteinization

Before the advent of commercially available methods, it was common to use two-phase, liquid-liquid partition with organic solvents and solvent mixtures, including methylene chloride, hexane, diethyl ether, ethanol/chloroform/water, methylene chloride/methanol, hexane/isopropanol, and cyclohexane/ethyl acetate.[108,169,288,555] Ethanol and methanol were also used to free 25(OH)D from DBP when measuring 25(OH)D.[108,288]

Today, the most widely used commercially available methods use acetonitrile to deproteinize the specimen and to denature DBP, thereby freeing vitamin D metabolites.[261] A method using immunoextraction for $1,25(OH)_2D$ has also been reported.[260,261,278]

Column Chromatography

The differences in their polarities, because of the number of hydroxyl groups, have been used to separate vitamin D and its metabolites. With three hydroxyl groups, $1,25(OH)_2D$ is more polar than 25(OH)D, with two hydroxyls, which is more polar than vitamin D, with one hydroxyl group.

Extracts have been purified by chromatography on minicolumns of silica, silicic acid, Sephadex LH-20, hydroxyalkoxypropyl Sephadex LH-20 (Lipidex 5000), celite, alumina, or some other absorbents.* Solid-phase extraction using octadecyl (C_{18})-silica was widely used for measuring $1,25(OH)_2D$.† The most popular method[459] used both a reversed-phase C_{18}-silica minicolumn and a normal-phase silica minicolumn to separate vitamin D metabolites. This method was modified by eliminating the silica cartridge and using "phase switching" with a single nonend-capped $C_{18}OH$ cartridge.[259]

Measurement of 25-Hydroxyvitamin D

Serum 25(OH)D has been measured by CPBA, competitive immunoassay (RIA, EIA, ICMA), or UV absorption after separation by HPLC. Determination by HPLC with UV absorption requires the appropriate HPLC equipment (see Chapter 6), more specialized training, and a larger sample. Most clinical laboratories measuring 25(OH)D have chosen the more familiar competitive immunoassays or CPBA. These assays are relatively easy to perform, use widely available reagents, and require only a small specimen. Although assays do not have difficulty in recognizing supranormal concentrations of 25(OH)D, measurement of subnormal and low normal concentrations is more difficult, requiring well-validated methods free from interference.

Radioimmunoassay. Development of an antiserum with equimolar cross-reactivity for $25(OH)D_2$ and $25(OH)D_3$ permitted the development of a competitive immunoassay (RIA) for 25(OH)D.[261,266] Previous antisera did not equally cross-react with D_2 and D_3 forms,[65] limiting their clinical usefulness. This antiserum was raised against a bovine serum albumin (BSA) conjugate of a vitamin D analogue lacking the side chain (23,24,25,26,27-pentanor vitamin D-C[22]carboxylic acid). A radioiodinated tracer was subsequently developed using a vitamin D analogue (3-aminopropyl derivative of vitamin D-C[22]-amide) and Bolton-Hunter reagent.[265] Samples and calibrators are

*References 5, 169, 247, 268, 288, 309, 348, 575.
†References 169, 263, 288, 293, 462, 575.

deproteinized with acetonitrile and analyzed directly without chromatography. Although the antiserum also recognizes 24,25(OH)$_2$D, 25,26(OH)$_2$D, and 25(OH)D-26,23-lactone, 25(OH)D results are comparable with HPLC because of the much lower concentration of these metabolites. RIA is reported to be less sensitive to interfering substances in serum extracts than CPBA using DBP. A second RIA has been approved by the Food and Drug Administration (FDA) for the measurement of 25(OH)D; however, this method does not appear to have equimolar cross-reactivity for 25(OH)D$_2$ and 25(OH)D$_3$.[262] Automated, nonisotopic immunoassays (even with pretreatment) for 25(OH)D are needed to increase the availability of 25(OH)D determinations.

Competitive Protein-Binding Assays with Vitamin D–Binding Protein. Before the development of immunoassays, 25(OH)D was measured primarily with CPBA with DBP as the specific binder, and with tritiated 25(OH)D$_3$ (>100 Ci/mmol) as tracer.[290,372,508] Rat serum, diluted approximately 1:50 000 (v/v), provides a convenient source of DBP. Assays based on DBP measure both 25(OH)D$_2$ and 25(OH)D$_3$. Assays that do not chromatographically isolate 25(OH)D measure other metabolites, including 25(OH)D$_3$-23,26-lactone, 24,25(OH)$_2$D, 25,26(OH)$_2$D, and to a lesser extent vitamin D, overestimating 25(OH)D by about 10% in normal individuals. It is important to verify that assays respond equally to 25(OH)D$_2$ and 25(OH)D$_3$. Serum extracts may contain other substances that cross-react in nonchromatographic assays using DBP, increasing the apparent concentration of 25(OH)D.* 25(OH)D concentrations are reported to be significantly higher when measured by CPBA when compared with RIA or HPLC.[338] An automated chemiluminescent assay is available for measuring 25(OH)D using DBP.[406]

HPLC and Ultraviolet Absorption. HPLC methods for 25(OH)D have used normal-phase chromatography on silica, reversed-phase chromatography on C_{18}-silica, or a combination of the two followed by quantification by UV absorption at 254 or 265 nm.† Most methods have required both extraction and preparative chromatography before HPLC. More recently, methods without preparative chromatography have been developed using gradient or isocratic reversed-phase HPLC and with photodiode-array UV detection.[14,580] A specimen of 0.5 to 1.0 mL is required because of the limited sensitivity of UV detection. Although HPLC methods allow 25(OH)D$_2$ and 25(OH)D$_3$ to be separated, independent determination is not of routine clinical value. HPLC is useful for validating the accuracy of immunoassays and CPBAs.

Measurement of 1,25-Hydroxyvitamin D

1,25(OH)$_2$D circulates at approximately 1/1000 the concentration of 25(OH)D and at significantly lower concentrations than other dihydroxylated metabolites, greatly complicating its determination in serum. The most widely used methods require extraction, chromatography, and quantification by radioreceptor assay (RRA) or RIA. RRAs have been widely used because of the high specificity of the vitamin D receptor (VDR) for 1,25(OH)$_2$D, whereas antisera have been less specific. The most widely used RRA and RIA are described and discussed in the following section.

Radioreceptor Assay. A flow diagram for the extraction, purification, and radioreceptor assay of 1,25(OH)$_2$D[259,261,459] is shown in Figure 49-19. Specimens (1 mL of serum or plasma) are deproteinized with acetonitrile, alkalinized and diluted, and applied to a C_{18}OH cartridge (solid-phase extraction). After washing with water and methanol/water (70:30), 25(OH)D and 24,24(OH)$_2$D are eluted with hexane/methylene chloride (90:10) and discarded. The column is washed with hexane/isopropanol (99:1), before the elution of 1,25(OH)$_2$D with hexane/isopropanol (95:5). The fraction containing 1,25(OH)$_2$D is evaporated, rehydrated, and assayed using an RRA with VDR from calf thymus. A nonequilibrium, delayed addition of tracer (5000 cpm of tritiated 1,25[OH]$_2$D$_3$) is used to lower the detection limit (2 to 5 pg/mL [4.8 to 12 pmol/L] with 1 mL of serum), followed by separation of bound and free tracer with dextran-treated charcoal. Recovery of the extraction, chromatographic, and other preparative procedures is monitored with a small amount of tritiated 1,25(OH)$_2$D$_3$.

This method is a substantial improvement over earlier methods using VDR from chick intestine. Calf thymus provides an unlimited, more reproducible source of VDR with several advantages over chick intestinal VDR.[270,287,459] Thymus receptor recognizes 1,25(OH)$_2$ D$_2$ and 1,25(OH)$_2$D$_3$ equally, unlike chick intestinal receptor, which underestimates the concentration of 1,25(OH)$_2$ D$_2$. VDR from thymus appears to be less sensitive than that from intestine to lipid and other nonspecific interferences extracted from serum, eliminating the need for extensive purification, including preparative HPLC. Patients treated with dihydrotachysterol may have falsely elevated concentrations of 1,25(OH)$_2$D when measured with chick intestinal receptor, but not with the thymus receptor assay.[554]

Radioimmunoassay. Before the development of the method described below, RIAs were not widely used in the United States because previous antisera: (1) did not reliably measure vitamin D status, since they discriminated between 1,25(OH)$_2$D$_2$ and 1,25(OH)$_2$D$_3$, and (2) cross-reacted with other vitamin D metabolites to a much greater extent than VDR requiring more extensive sample purification, including preparative HPLC.[63,111,139,233,261]

The RIA described below is more convenient than the RRA for 1,25(OH)$_2$D[261,264] because a radioiodinated tracer eliminates the need for liquid scintillation, and the antiserum eliminates the need to prepare VDR from calf thymus. The RIA uses a previously developed antiserum[191] with 1% to 2% cross-reactivity with the more abundant, non-1-hydroxylated vitamin D metabolites and a ^{125}I-labeled tracer prepared from 1,25(OH)$_2$-24,25,26,27, tetranor-

*References 65, 96, 169, 336, 367, 605.

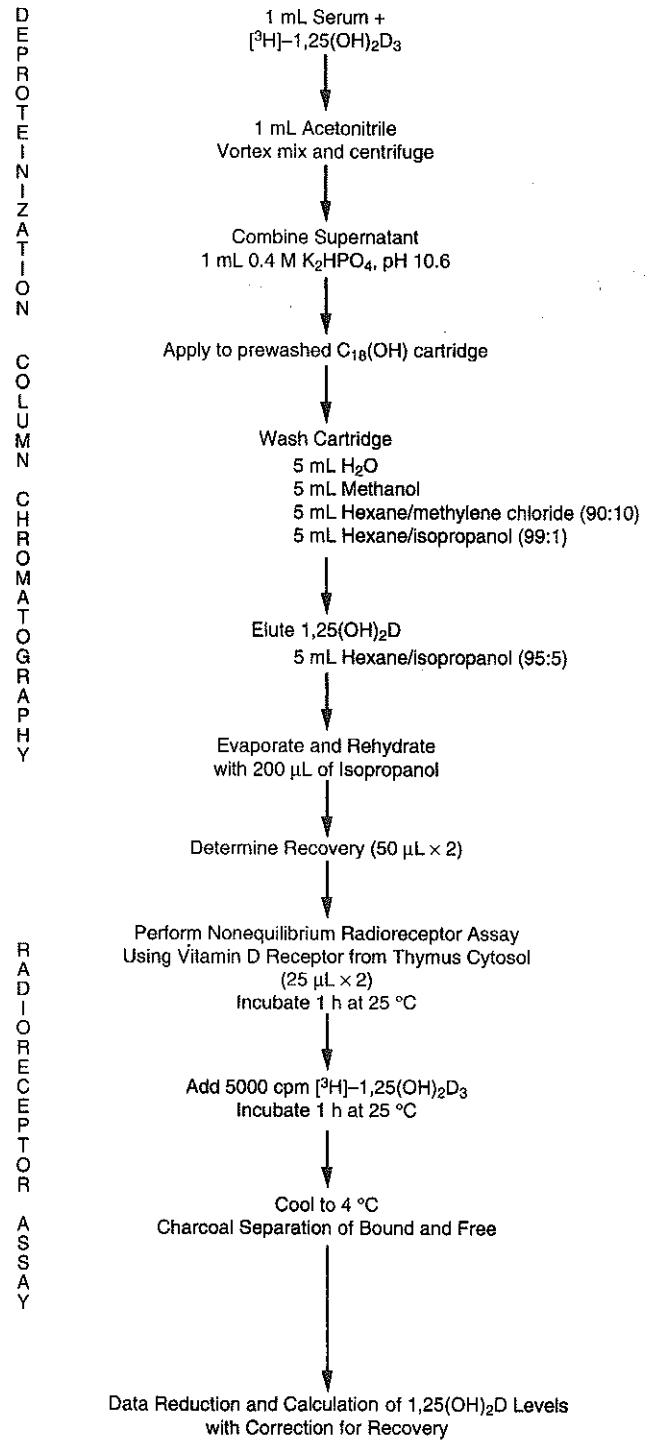

Figure 49-19 Flow diagram outlining determination of 1,25-dihydroxyvitamin D using a single-column extraction and purification method and a nonequilibrium radioreceptor assay with vitamin D receptor from calf thymus.

C(23)-carboxylic acid and radiolabeled Bolton-Hunter reagent. Before analysis, specimens are deproteinized with acetonitrile, oxidized with sodium metaperiodate, and purified using C_{18}-OH and silica cartridges. Sodium metaperiodate is necessary to eliminate interference by 24,24$(OH)_2$D and 25,26$(OH)_2$D by oxidizing them to their aldehyde and ketone forms, which are easily removed by chromatography. A silica column was added to the single C_{18}-OH cartridge used with the radioreceptor assay to reduce interference in the RIA. With this RIA, 1,25$(OH)_2$ D_2 is about 70% as potent as 1,25$(OH)_2D_3$. Recovery of individual samples is not determined, although calibrators are prepared in a stripped serum base and treated identically to samples. The method does cross-react (13% to 25%) with a number of 1-hydroxylated metabolites, including 1,24,25$(OH)_3$D, 1,25,26$(OH)_3$D, and 1,25$(OH)_2$D-26,23-lactone. 1,25$(OH)_2$D-26,23-lactone is a significant metabolite with a concentration of 0% to 30% of 1,25$(OH)_2D_3$. A modification of this method using a single C_{18}-OH "extra clean" cartridge is commercially available.[153]

Another commercially available RIA has been developed that uses selective immunoextraction of 1,25$(OH)_2$D.[260,261,278] This method is reported to have greater cross-reactivity with the 1-hydroxylated metabolites, including 1,25-dihydroxyvitamin D_3-26,23-lactone[260,261] and calcipotriol,[278] which is used for treating psoriasis. Apparent concentrations of 1,25$(OH)_2$D are significantly higher with this method than the RRA in patients with hypoparathyroidism receiving vitamin D treatment, patients with biliary atresia, vitamin D–intoxicated subjects, and some normal specimens.[261]

Troubleshooting Vitamin D Assays

Methods requiring extraction and chromatography should be monitored for recovery of the vitamin D metabolites of interest and for solvent or column blanks. For the RRA assay, recovery is monitored and the final result is corrected for losses by the addition of a small, known amount of tritiated 1,25$(OH)_2D_3$ before extraction of specimens. Care must be taken to ensure that D_2 and D_3 metabolites are recovered equally, providing a total measurement of 25(OH)D or 1,25(OH)D. Solvents, chromatographic materials, and cartridges may contain substances that interfere with quantification of vitamin D metabolites by CPBA, RIA, and RRA or UV absorption after HPLC, resulting in an overestimation of vitamin D metabolites. Any interferences can be monitored by treating a water blank identically to the specimens. Undetectable concentrations of vitamin D in this blank verify the absence of positive interference.

Calibrators for vitamin D assays should be prepared from stock solutions whose concentration and purity are checked by UV spectrophotometry.[270] Stock solutions are suitable if the ratio of the absorbance at 264 to 228 nm is greater than or equal to 1.5. Stock solutions are adjusted using a molar extinction coefficient of 18,200 L/mol/cm for vitamin D_3 metabolites at 264 nm. Tracers used for recovery must be pure to determine recovery accurately. Both calibrators and tracers may be purified by HPLC.

Specimen Requirements

Serum is typically used for measuring vitamin D metabolites, although plasma is generally acceptable for assays using extraction and chromatography. Once separated from the

clot, serum is relatively stable at both room temperature and 4 °C; however, specimens should be frozen if the analysis is delayed.[339] Vitamin D metabolites in serum or plasma do not appear to be sensitive to light and do not require special handling in the laboratory.

Reference Intervals

Reference intervals for vitamin D are method-dependent, but representative ones are:
25(OH)D: 10 to 65 ng/mL (25 to 162 nmol/L)
$1,25(OH)_2D$: 15 to 60 pg/mL (36 to 144 pmol/L)

The lower limit of the reference range for 25(OH)D of 10 to 15 ng/mL (25 to 37 nmol/L) has been increasingly criticized as inappropriately low. Although a decision level for vitamin D insufficiency has not been determined, concentrations of less than 20 to 30 ng/mL (50 to 75 nmol/L) are associated with increased PTH[352,534] and reduced calcium absorption.[248] The recent NHANES III study reported an unexpectedly high prevalence of vitamin D insufficiency.[94,346] For example, vitamin D insufficiency (25 (OH)D <20 ng/mL [50 nmol/L]) was exceedingly common during the winter in adult (30 years and older) Caucasian men (15%) and women (30%) living in the South. Vitamin D insufficiency was most common in Blacks, with the prevalence in Hispanics between Caucasians and Blacks.

Circulating concentrations of 25(OH)D are increased by exposure to sunlight and show seasonal variation, with the highest concentrations in summer or fall and the lowest concentrations in winter or spring.[522] Concentrations are influenced by latitude, sunscreen use, and skin pigmentation.[257,258] Serum 25(OH)D concentrations of 100 ng/mL (250 nmol/L) are not uncommon in lifeguards.

Concentrations of vitamin D metabolites vary with age and are increased in pregnancy.[216,454] Concentrations of $1,25(OH)_2D$ are higher in pregnancy and in children than adults, with the highest concentrations occurring during periods of greatest growth.[6,360,373,476,536] Although 25(OH)D and $1,25(OH)_2D$ concentrations have been reported to decrease with age, this decline may be a consequence of poor nutrition, reduced exposure to sunlight, and declining health. Concentrations of these metabolites have been unchanged with age in studies limited to healthy and active subjects.[162,418]

Calcitonin

Calcitonin is secreted by the parafollicular or C cells, which arise from the neural crest and are distributed throughout the thyroid gland. These cells are included in the APUD (*a*mine *p*recursor *u*ptake and *d*ecarboxylation) family, which explains the association of medullary thyroid carcinoma (a tumor of the C cells) and other tumors of the APUD family in multiple endocrine neoplasia type-2A and -2B (MEN-2A and MEN-2B). Release of calcitonin is stimulated by calcium, and it has been used pharmacologically as an inhibitor of bone resorption.

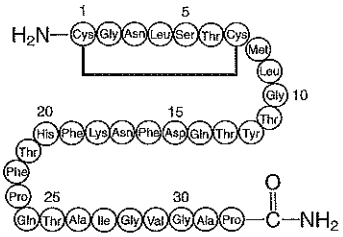

Figure 49-20 Amino acid sequence of calcitonin.

Biochemistry and Physiology

Calcitonin is a 32–amino acid peptide (MW = 3418) with an N-terminal disulfide bond linking cysteine residues 1 and 7 and a C-terminal proline-amide (Figure 49-20). The C-terminal portion of the molecule, with its proline-amide residue, the disulfide bond between residues 1 and 7, and the methionine residue at position 8 are necessary for biological activity. The amino-terminal amino acids are highly conserved; five of the first nine amino acids are identical in all species. In humans, porcine calcitonin is 1/10 as active as human calcitonin, whereas salmon calcitonin is 10 times more potent.

The physiological control of calcitonin secretion is incompletely understood. Calcium appears to be the most important secretagogue; an increase in serum calcium increases calcitonin. In some animals, a number of other factors, including the hormones gastrin, cholecystokinin, glucagon, and secretin, can stimulate calcitonin secretion; the physiological role of these hormones in humans is uncertain.

Pharmacological doses of calcitonin reduce serum calcium and phosphate concentration primarily by inhibiting osteoclastic bone resorption. Recognition of this pharmacological effect has resulted in the use of salmon and human calcitonin to reduce bone resorption in patients with Paget's disease and osteoporosis and as a treatment for hypercalcemia in diseases associated with increased bone resorption. Pharmacological doses of calcitonin also decrease the renal tubular reabsorption of calcium and phosphate.

Despite these pharmacological effects, the physiological role of calcitonin in adults is uncertain. No apparent alterations in bone or mineral metabolism are evident in humans with calcitonin deficiency or excess. Calcitonin may be important during periods of calcium stress in fetuses or young children or during pregnancy or lactation, as evidenced by the higher concentrations observed during these physiological states.

Multiple forms of circulating calcitonin have been reported in normal individuals and patients with medullary thyroid carcinoma (MTC) or nonthyroidal malignancies.* Much of the immunoreactive calcitonin generally migrates as larger forms rather than with monomeric calcitonin. A

*References 30, 151, 224, 390, 486, 528, 566.

sulfoxide of the monomer, dimers, glycosylated forms, and precursors have been proposed to explain this heterogeneity.[30,279,528,566]

Clinical Significance

MTC occurs as a sporadic disease and as part of the syndromes of MEN-2A, MEN-2B, and familial MTC (FMTC).[8,71,150,381] MEN-2A and MEN-2B are autosomal dominant inherited multiglandular syndromes with age-related penetrance and variable expression. All forms of MTC combined account for 5% to 10% of thyroid malignancies. Sporadic MTC is believed to comprise approximately 75% of all MTC. The routine measurement of serum calcitonin in nodular thyroid diseases assists in detecting unsuspected sporadic MTC.[158,421,463] With the advent of genetic testing for MEN-2A, MEN-2B, and FMTC, calcitonin is primarily used for diagnosing sporadic MTC or the index case in familial MTC or for monitoring MTC.

In approximately 95% of individuals with MEN-2A, MEN-2B, and FMTC, mutations are identified with genetic testing of the coding sequence of the *RET* proto-oncogene transmembrane tyrosine kinase receptor.* Genetic testing provides the most sensitive and specific method for detection of the disorder in family members of the index case; and unlike calcitonin monitoring, it does not require annual testing. Genetic testing is also justified in sporadic cases of MTC, as 5% to 10% carry germline *RET* mutations.

Many patients with MTC have increased basal concentrations of calcitonin (after biological penetrance), but provocative testing using calcitonin secretagogues increases the sensitivity of detecting MTC and C-cell hyperplasia.[27,296,530,599] Calcium,[489] pentagastrin,[219] or a combination of calcium and pentagastrin[530,599] have been the most commonly used agents for stimulating calcitonin secretion. Specificity is also increased with provocative testing.[54] Minimally increased concentrations that are not stimulated after provocative testing should be questioned. Resolution may require the use of other provocative agents, confirmation that a proper stimulation test was conducted (e.g., determination of serum calcium when calcium is used as the stimulant), or the use of different methods for measuring calcitonin. The effectiveness of surgery is often monitored by serial measurement of basal and, preferably, stimulated calcitonin concentrations.[565,600] Increased calcitonin concentrations are generally believed to be indicative of persistent or recurrent disease, although many of these patients remain asymptomatic for years.

Calcitonin concentrations are increased in various nonthyroidal cancers (Box 49-11). Although increased calcitonin is most often associated with tumors arising from tissues derived from the neural crest, it may also be increased in other malignancies. These include intestinal, bronchial, and gastric carcinoids; carcinoma of the lung, especially oat-cell or small-cell carcinoma; melanoma and pheochromocytoma; and pancreatic and breast carcinoma.[135,391,507,591]

BOX 49-11 Increased Circulating Levels of Calcitonin

C-cell hyperplasia
Medullary thyroid carcinoma
Nonthyroidal cancers
  Oat-, small-cell carcinomas
  Other malignancies
Acute and chronic renal failure
Hypercalcemia
Hypergastrinemia and other gastrointestinal disorders
Pulmonary disease

Elevated concentrations of calcitonin or increased responsiveness to stimulation have also been reported in acute and chronic renal failure, hypercalcemia, hypergastrinemia and other gastrointestinal disorders, pulmonary disease, and severe illness.[32,135,604]

Measurement of Calcitonin

Measurement and interpretation of serum calcitonin are complicated by the heterogeneity circulating of calcitonin and large differences in the sensitivity and specificity of calcitonin immunoassays.

Radioimmmoassays

Historically, calcitonin was measured primarily by RIA. Using RIA, the upper limit of the normal reference interval varied from 20 to 1000 pg/mL (ng/L) or more.[135,249] Differences in assay sensitivity, sensitivity to matrix effects and specificity, and the heterogeneity of calcitonin probably explain these differences. Basal calcitonin concentrations in normal individuals have generally been less than 100 pg/mL (ng/L) with the newer and more sensitive, homologous RIAs. Normal concentrations of less than 50 pg/mL (ng/L) have been reported by investigators with certain RIAs or after concentration and partial purification of specimens using affinity chromatography with immobilized calcitonin antiserum before RIA.[614]

Upper reference limits of 20 and 25 pg/mL (ng/L) for women and men, respectively, have been reported using a highly sensitive RIA with detection limit of 3 pg/mL (ng/L).[170,430] Other investigators reported normal concentrations of less than 20 pg/mL (ng/L) using preparative chromatography on silica columns to extract and partially purify calcitonin from 15 to 20 mL of plasma.[53]

Noncompetitive Immunoassays

More recently, noncompetitive immunoassays (IRMA, ELISA, and ICMA) have been reported for calcitonin.* Com-

*References 8, 71, 134, 150, 199, 381, 600.

*References 235, 390, 431, 516, 517, 596, 608, 622.

pared with earlier RIAs, these methods provide improved sensitivity and specificity for the diagnosis of MTC.* With most noncompetitive methods, basal concentrations of calcitonin in normal individuals are less than 10 to 20 pg/mL (ng/L). Investigations of two-site assays indicate that they may also recognize multiple forms of immunoreactive calcitonin.[390,608]

Automated noncompetitive chemiluminescent (ICMA) methods have recently been reported using acridinium ester or ALP with 1,2-dioxetane phosphate.

Reference Intervals

The basal and pentagastrin-stimulated reference intervals for normal men, women, and athyroidal patients for a sensitive, noncompetitive chemiluminescent method are listed below[174]:

Basal concentrations of serum calcitonin:

Men:	<8.8 pg/mL (ng/L)
Women:	<5.8 pg/mL (ng/L)
Athyroidal:	<0.5 pg/mL (ng/L)

Provocative testing

Pentagastrin†

Normals:	<30 pg/mL (ng/L) (N = 20)
Athyroidal:	<0.5 pg/mL (ng/L) (N = 10)

Reference intervals for calcitonin are dependent on the method. Basal and stimulated (calcium and pentagastrin) ranges should be determined for normal individuals and athyroidal individuals, by gender, for each method.

Gender, age, growth, pregnancy, lactation, and ingestion of food have been reported to influence calcitonin concentrations in normal individuals. Most investigators[170,249] have observed higher concentrations of basal and stimulated calcitonin in men than in women. The effect of age is less certain, as basal and stimulated concentrations have been reported both to decline and to remain unchanged with age.[137,430,563] Higher concentrations have been reported during pregnancy and lactation[525] and in children and infants.[51,306] Food ingestion has been reported both to increase and to have little effect on the concentration of circulating calcitonin.[53,518]

Parathyroid Hormone–Related Protein

PTHrP was discovered in 1987 by investigators studying the mechanism by which certain cancers produce humoral hypercalcemia of malignancy (HHM).‡

Biochemistry and Physiology

PTHrP is derived from a gene on chromosome 12 that is distinct from the PTH gene on chromosome 11. Three isoforms of 139, 141, and 173 amino acids are predicted by alternative messenger RNA (mRNA) splicing (Figure 49-21). The N-terminal end of the molecule shows close homology to PTH (8 of the first 13 amino acids being identical). The remainder of the PTHrP molecule shows little homology with PTH. The PTH-like activity of PTHrP is contained within the N-terminal amino acids (PTHrP[1-36]).

The common N-terminal explains the ability of PTHrP to interact with the PTH/PTHrP receptor, mimicking the biological actions of PTH in classic target tissues, including bone and kidney. Like PTH, PTHrP causes hypercalcemia and hypophosphatemia and increases urinary cyclic AMP. However, when compared with patients with primary hyperparathyroidism, patients with PTHrP-induced hypercalcemia have lower concentrations of $1,25(OH)_2D$ and more typically have metabolic alkalosis (instead of hyperchloremic metabolic acidosis), reduced distal tubular calcium reabsorption, and reduced and uncoupled bone formation.

The multitude of basic residues in PTHrP suggests that it may undergo extensive posttranslational processing.[419] Forms of PTHrP containing the following amino acids have been detected in serum: (1) PTHrP(1-36) measured by N-terminal assays, (2) PTHrP containing N-terminal and midregion amino acids measured with noncompetitive immunoassays against PTHrP(1-74 or 1-86), (3) midregion fragments, beginning at position 38 and extending 70 to 80 amino acids, measured with midregion assays, and (4) carboxyl fragments, beginning at position 107, measured with antiserum directed against PTHrP(109 to 138). Midregion and carboxyl forms may exert biological actions distinct from the PTH-like actions associated with the N-terminal region.

Besides its endocrine role in the pathophysiology of HHM, PTHrP appears to participate in normal physiology by acting locally on cells or tissue as an autocrine or paracrine factor.[353,419,432] PTHrP is widely expressed in most normal tissues of fetuses and adults.[315,448,579] Although it is unlikely that the low circulating concentrations of PTHrP have a significant effect on calcium homeostasis in normal adults, PTHrP may exert endocrine effects on calcium homeostasis during fetal life and lactation.[535] Breast milk contains high concentrations of PTHrP. Examination of the physiological effects of PTHrP identifies several themes: (1) PTHrP regulates transepithelial calcium transport; (2) PTHrP is a potent, smooth muscle relaxant; (3) PTHrP regulates growth, differentiation, and development; and (4) PTHrP's role in many tissues is unknown.

Clinical Significance

Hypercalcemia associated with malignancy is the second most common cause of hypercalcemia. This frequent paraneoplastic syndrome is believed to occur primarily through

*References 27, 235, 296, 390, 431, 596.

†Gender-based provocative intervals are preferable because of the differences in basal and stimulated calcitonin between men and women. Because pentagastrin is not readily available in the US, studies are needed to define gender-based ranges for the more widely used calcium stimulation tests.

‡References 90, 92, 353, 364, 389, 420, 542, 546, 616.

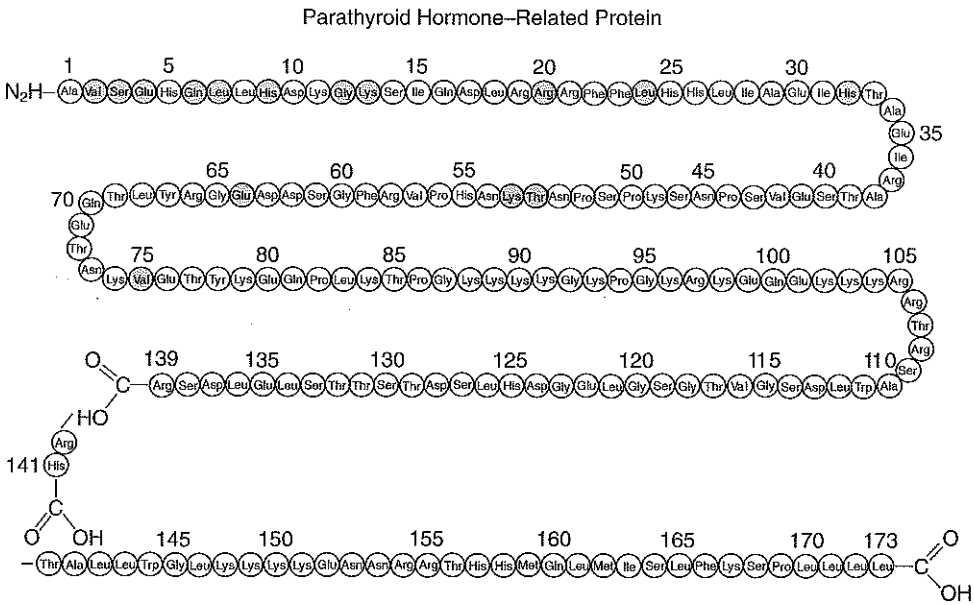

Figure 49-21 Amino acid sequence of PTHrP. Although the exact length of circulating PTHrP is unknown, proteins of 139, 141, and 173 amino acids have been predicted from alternative splicing events. The black circles show amino acids that are identical in PTH and PTHrP. *(Modified from Hendy GN, Goltzman D. Parathyroid hormone-like peptide. In: Endocrinology and metabolism inservice, Vol 9. Washington, DC: American Association for Clinical Chemistry, 1991:9-24.)*

two mechanisms: HHM and local osteolysis. Patients with HHM account for approximately 75% to 80% of patients with hypercalcemia associated with malignancy. HHM is common in patients with squamous (lung, head and neck, esophagus, cervix, vulva, and skin), renal, bladder, and ovarian carcinomas. Hypercalcemia due to skeletal metastases and local osteolysis are common in breast cancer and multiple myeloma, lymphomas, and other hematological malignancies. The hypercalcemia of a subset of lymphomas (human T-cell leukemia virus-1) appears to be caused by HHM. Breast carcinomas may cause hypercalcemia by HHM and/or skeletal metastases with local osteolysis. It is now well established that PTHrP is the principal mediator of HHM. After being secreted by tumors, PTHrP circulates and acts on its target tissues (skeleton and kidney) as an endocrine hormone causing hypercalcemia.

PTHrP determinations are usually considered investigational, because HHM nearly always occurs in advanced disease when the diagnosis is obvious. The need for PTHrP determinations may increase if it becomes important in prognosis,[577] selection of therapy, or monitoring.

Measurement of PTHrP

A number of competitive immunoassays have been used for measuring PTHrP in sera from patients with HHM. For example, N-terminal (PTHrP[1-34]), midregion (PTHrP [37-67, 37-74]), and C-terminal (PTHrP[109-138]) competitive RIAs have been developed.* Of the competitive immunoassays, the N-terminal assays have been used most widely. Affinity chromatography with immobilized antisera against PTHrP,[82] reversed-phase chromatography,[294] and other purification techniques have been used to improve the sensitivity and specificity of these competitive RIAs. C-terminal assays are elevated in patients with renal insufficiency.[91]

More sensitive and noncompetitive immunoassays (IRMAs) have also been developed.* Currently available assays use antibodies against PTHrP (sequences 37-74, 1-40, 1-40, 1-34, 1-40, and so on) as capture antibodies. Their radiolabeled signal antibodies are against PTHrP (sequences 1-36, 60-72, 57-80, 37-67, 50-83, and so on), respectively. The limit of detection for these assays is reported to be from 0.1 to 1.0 pmol/L.

Specimen Requirements

PTHrP is unstable in serum and plasma at 4 °C and at room temperature unless collected in the presence of protease inhibitors.[195,276,330,422] A combination of aprotinin, leupeptin, pepstatin, and EDTA provides the greatest protection.[422] In general, specimens should be collected with protease inhibitors and kept on ice. Serum or plasma should be promptly separated from the clot and/or cells and frozen.

Reference Intervals

PTHrP: 1.3 pmol/L or less.

PTHrP concentrations in normal persons are dependent on both the assay and specimen collection. Concentrations

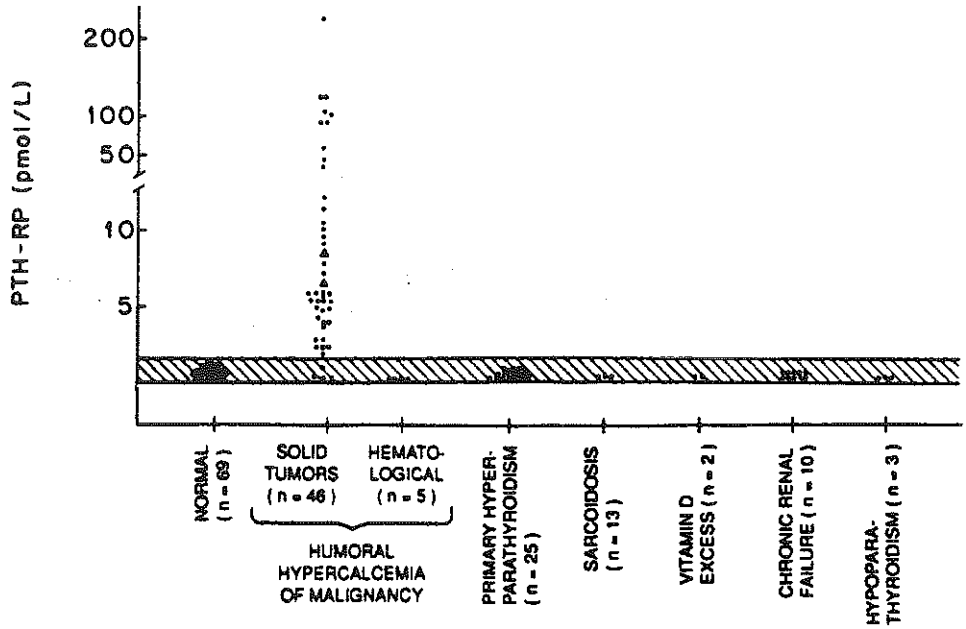

Figure 49-22 PTHrP in normal subjects and patients with malignancies and other disorders. Hatched area indicates the normal reference interval. *(Adapted from Pandian MR, Morgan CH, Carlton E, Segre GV. Modified immunoradiometric assay of parathyroid hormone-related protein: clinical application in the differential diagnosis of hypercalcemia. Clin Chem 1992;38:282-88.)*

in normal individuals range from undetectable to up to 5 pmol/L.* With sensitive noncompetitive immunoassays, concentrations of up to approximately 1 to 2 pmol/L have been reported in normal subjects.† PTHrP is reported to be detectable in approximately 50% to 80% of healthy individuals with the most sensitive methods.[90,195,422,452]

Interpretation

PTHrP is increased in 50% to 90% of patients with hypercalcemia associated with malignancy (Figure 49-22).‡ In addition to squamous cell carcinomas of the lung, head and neck, esophagus, cervix, skin, and other sites, concentrations have been elevated in a wide variety of malignancies, irrespective of their source or histology. Increased concentrations of PTHrP have been found in breast, renal, bladder, and ovarian carcinomas. Concentrations are elevated in a number of endocrine malignancies with hypercalcemia, including pheochromocytoma and islet carcinomas. PTHrP is elevated in hypercalcemic patients with adult T-cell lymphomas/leukemia and B-cell lymphoma.[277] PTHrP concentrations have been less frequently elevated in patients with hypercalcemia and other hematological malignancies (e.g., multiple myeloma).

PTHrP is undetectable or normal in most, but not all, patients with malignancy not associated with hypercalcemia.* Increased concentrations of PTHrP have been reported to precede hypercalcemia in some patients with malignancy. Concentrations are normal in patients with primary hyperparathyroidism, hypoparathyroidism, miscellaneous causes of hypercalcemia, and chronic renal failure (with noncompetitive methods).

INTEGRATED CONTROL OF MINERAL METABOLISM

The metabolism of calcium is linked intimately with that of phosphate (Figure 49-23).[23,41] The homeostatic mechanisms are directed principally toward the maintenance of normal extracellular calcium and phosphate concentrations, which sustain the extracellular and intracellular processes and provide substrate for skeletal mineralization. The parathyroid gland responds to a decrease in free calcium concentration within seconds. During a time of calcium deprivation, the increase in serum PTH rapidly alters both renal and skeletal metabolism.

Renal Handling of Calcium and Phosphate

Of the approximately 10 g (250 mmol) of calcium filtered by the kidneys each day, 65% is reabsorbed in the proximal tubule. Calcium reabsorption here is closely linked to sodium and is independent of PTH. Approximately 10% to

*References 82, 91, 251, 294, 422, 451.
†References 90, 91, 195, 422, 451, 452.
‡References 82, 91, 92, 251, 294, 422, 451, 616.

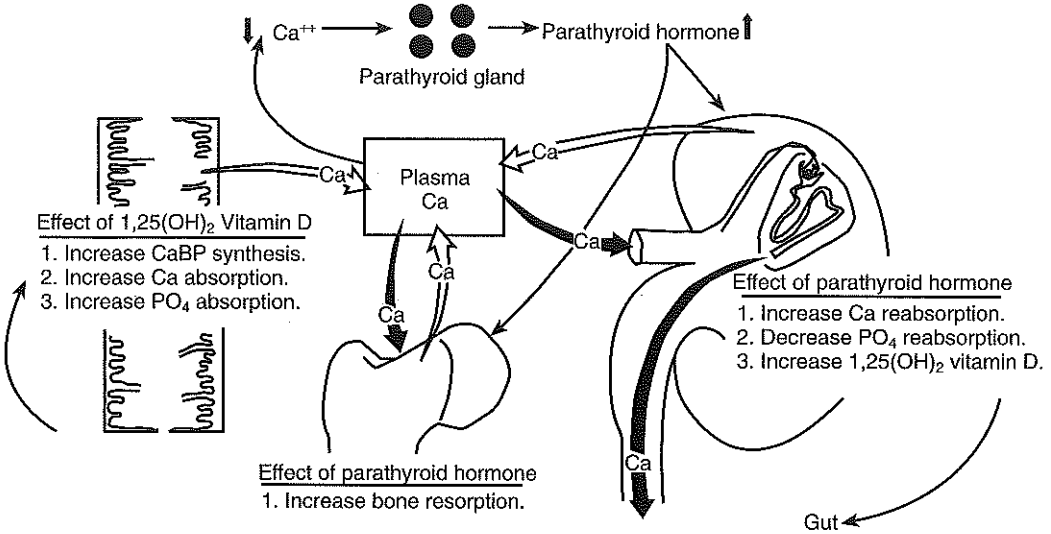

Figure 49-23 Integrated control of mineral metabolism. *CaBP,* Calcium-binding protein.

20% of calcium is reclaimed in the thick ascending loop of Henle and 5% to 10% in the distal convoluted tubule. PTH enhances calcium reabsorption at the distal tubule, presumably through a cyclic AMP mechanism. A small portion of filtered calcium, about 5%, is reabsorbed in the collecting duct via a PTH-independent mechanism.

In contrast to the calcium-conserving effect of PTH on the kidneys, PTH increases renal phosphate excretion at the proximal tubule by directly lowering the renal phosphate threshold. Approximately 6.5 g (210 mmol) of phosphate is filtered by the kidneys each day. Normally, 85% to 90% is reabsorbed by the renal tubules (proximal and distal convoluted tubule). PTH is one of the most important factors regulating the renal phosphate threshold and hence the serum phosphate concentration.

Intestinal Absorption of Calcium and Phosphate

PTH also increases intestinal calcium absorption by increasing $1,25(OH)_2D$. PTH is a major trophic factor for renal 25(OH)D-1α-hydroxylase. It increases the conversion of 25(OH)D to the active vitamin D metabolite, $1,25(OH)_2D$. Calcium is absorbed principally in the duodenum, although it can also be absorbed by the distal small bowel and colon. About 30% of a daily calcium intake of 1 g (25 mmol) is absorbed. Approximately 100 mg (2.5 mmol) of calcium is secreted into gut lumen by intestinal secretion; therefore net calcium absorption is 200 mg (5.0 mmol)/day. Calcium is absorbed by passive diffusion and by an active transport system. It is estimated that passive diffusion accounts for absorption of about 10% of ingested calcium per day. Active calcium absorption in the duodenum is under the control of $1,25(OH)_2D$. This vitamin D metabolite increases the intestinal cell synthesis of a calcium-binding protein (CaBP), which enhances the net absorption of ingested calcium.

Dietary phosphate intake is usually 1.2 to 1.4 g (39 to 45 mmol)/day, nearly twice the recommended intake, of which approximately 60% to 70% is absorbed, principally in the jejunum. As with calcium, both passive and active transport systems exist; $1,25(OH)_2D$ is the principal regulator of the active transport of phosphate. PTH-stimulated synthesis of $1,25(OH)_2D$ thus offsets the phosphaturic effect of PTH. The prevailing serum phosphate concentration also modulates renal 25(OH)D-1α-hydroxylase. Phosphate depletion or hypophosphatemia stimulates formation of $1,25(OH)_2D$ by the kidneys. In general, at pharmacological concentrations, calcitonin has the opposite effect of PTH. It is unclear, however, if calcitonin has any physiological role in mineral homeostasis in adult humans.

Bone Metabolism

PTH also has an acute effect on the skeleton. Acutely, PTH decreases osteoblastic collagen synthesis, but osteoclastic bone resorption increases, with a net increase of mineral (calcium and phosphate) release from bone into the ECF. PTH is able to act directly on osteoblasts by interacting with their PTH receptors. The effect of PTH on osteoclasts appears to be indirect, through local mediators produced by the osteoblast (e.g., RANK ligand and OPG) or released from the bone matrix (e.g., TGF-β). Prolonged calcium deprivation results in enhanced recruitment of osteoclasts and an increased number of mature osteoclasts, which continue to resorb bone, releasing calcium and phosphate and bone matrix peptides such as pyridinium collagen cross-links. Prolonged exposure to PTH eventually also increases osteoblast activity, thus increasing markers of bone formation such as ALP and osteocalcin.

Magnesium

Magnesium is efficiently absorbed in the intestinal tract (most efficiently in the distal small bowel). During normal

dietary magnesium intake, approximately 30% to 40% of magnesium is absorbed. Magnesium is absorbed by both active and passive transport.

No hormone or factor has been described as regulating magnesium homeostasis. About 25% to 35% of filtered magnesium is passively reabsorbed in the proximal convoluted tubule, where reabsorption is linked closely to sodium and calcium transport. The major site of active reabsorption is the thick ascending loop of Henle, where 60% to 75% of magnesium is reabsorbed. During times of magnesium deprivation, magnesium essentially disappears from the urine (<0.5 mmol/day). The renal threshold for magnesium is close to the filtered load. When magnesium intake is excessive, any amount greater than this maximum is excreted.

METABOLIC BONE DISEASES

Metabolic bone diseases result from a partial uncoupling or imbalance between bone resorption and formation. Decreased bone mass, or *osteopenia,* is more common than abnormal increases of bone mass. The most prevalent metabolic bone diseases are osteoporosis, osteomalacia and rickets, and renal osteodystrophy. Osteoporosis, the most prevalent metabolic bone disease in developed countries, is characterized by loss of bone mass, microarchitectural deterioration of bone tissue, and increased risk of fracture. Rickets and osteomalacia, which are more common in the less-developed countries, are characterized by defective mineralization of bone matrix. Renal osteodystrophy is a complex condition that develops in response to abnormalities of the endocrine and excretory functions of the kidneys. These three metabolic bone diseases and Paget's disease, a localized bone disease, are discussed below followed by laboratory markers of bone metabolism.

OSTEOPOROSIS

Osteoporosis is the most prevalent metabolic bone disease in the United States and results in 1.5 million fractures each year.[24,464] Osteoporosis is associated with an increased risk for vertebral, hip, and distal forearm fractures. At age 50, women have a lifetime fracture risk (any of the above three sites) of about 40%. Men have a lifetime fracture risk of approximately one third that of women. Since trabecular bone turns over at five to seven times the rate of cortical bone, fractures of bones that are predominantly trabecular (vertebra and distal forearm) occur earlier in life. One third of women older than 65 years suffer vertebral crush fractures. Vertebral crush fractures can occur acutely and result in disabling pain and discomfort. Long-term complications include immobility and loss of height. Secondary problems include protuberant abdomen, chronic constipation, and loss of self-esteem. Fractures of bone with more cortical bone (proximal femur or hip) occur later in life. For women, the lifetime risk of hip fracture is 15%. The mortality rate accompanying hip fracture may be as high as 20%. Twenty-five percent of the survivors are confined to long-term care in nursing homes. The cost of medical care for osteoporosis was estimated to be $17 billion in 2001.

Peak bone mass is normally attained by 30 years of age and decreases after 35 to 45 years of age in both men and women. The amount of bone attained during growth is an important determinant of whether clinical osteoporosis develops later in life. Exercise and adequate nutrition play important roles in attaining and maintaining skeletal mass. During early adult life, bone formation is coupled to bone resorption so that bone mass remains stable. Aging is a major risk factor, because after 35 to 40 years of age bone resorption slightly exceeds bone formation so that approximately 1% of the skeletal mass is lost per year. In women, the decrease in sex steroids at menopause accelerates bone loss (postmenopausal osteoporosis) to about 2% per year. Osteoporosis is usually due to either inadequate bone formation during growth or a pathophysiological process that impairs osteoblastic bone formation or increases bone resorption. Osteoporosis is most commonly encountered in postmenopausal women. Advanced age, female gender, and sex steroid deficiency are prominent risk factors. Other risk factors include a family history of osteoporosis, alcohol abuse, smoking, and chronic diseases.

After decreased bone mass is documented by bone mass measurements, the diagnostic work-up is directed at determining the cause (Box 49-12). Most often the cause is attributed to age ("senile" osteoporosis), postmenopausal osteoporosis, or both, but it may be secondary to chronic diseases, drug therapies, or other causes. If osteoporosis is inconsistent with age or gender (such as in a middle-aged man or a premenopausal woman), laboratory testing should be performed to exclude other secondary causes of osteoporosis including hyperthyroidism, Cushing's syndrome, hypogonadism, primary hyperparathyroidism, and multiple myeloma. Chronic excess of thyroid hormone, cortisol, or PTH may cause osteoporosis. Long-standing hyperthyroidism or excessive thyroid hormone replacement increases bone resorption more than formation leading to osteoporosis. Cortisol markedly decreases bone formation and causes an increase in bone resorption. Patients with Cushing's syndrome may have severe osteoporosis. More commonly, patients receiving glucocorticoid therapy for diseases like asthma and rheumatoid arthritis may have disabling osteoporosis. Hyperparathyroidism occurs most commonly in postmenopausal women and may lead to osteoporosis. Multiple myeloma not uncommonly presents with vertebral crush fractures, and osteoporosis must be considered in these patients.

Bone markers are used to assess bone turnover (resorption or formation) in patients with osteoporosis. This testing is useful for identifying osteoporotic individuals with elevated bone resorption and for predicting and assessing the response to therapy. Markers of bone resorption include collagen cross-links (N-telopeptide, deoxypyridinoline, or C-telopeptide). Because bone resorption and formation are coupled, markers of bone formation (BAP and serum osteo-

BOX 49-12 Causes of Osteoporosis

Failure to develop normal skeletal mass during growth and development because of poor nutrition or inadequate exercise
Endocrine deficiency or excess
  Estrogen or testosterone deficiency

Immobilization or weightlessness
Hematological malignancies (multiple myeloma)
Inherited defects of collagen synthesis (osteogenesis imperfecta)
Systemic mastocytosis
Heparin therapy
Rheumatoid arthritis
Idiopathic juvenile osteoporosis

calcin) are also increased in high-turnover osteoporosis. Elevated markers of bone turnover indicate increased bone formation and/or resorption, but are not diagnostic of osteoporosis. They are best used to monitor therapy for osteoporosis; a 30% or greater decrease in a bone marker suggests efficacy of therapy. Serial bone mass measurements are made every 1 to 3 years during therapy; bone mass changes slowly and the imprecision of the measurements allows detection of only relatively large changes. The measurements are nonetheless considered useful in monitoring therapy.[284]

Prevention of osteoporosis is an important goal. Adequate nutrition and exercise during growth allow achievement of optimal bone mass. High calcium intake (1000 [24.9 mmol] to 1500 mg [37.4 mmol]/day), adequate vitamin D (400 to 800 U/day), and a regular exercise program are helpful in preventing osteoporosis. Calcium supplements slow the loss of cortical bone but are less effective in preventing trabecular bone loss.

Treatment of osteoporosis depends on the cause. In secondary osteoporosis, treatment is directed at the underlying condition. Most therapies for the treatment of postmenopausal osteoporosis are directed at decreasing osteoclastic bone resorption. Antiresorptive therapies include bisphosphonates (alendronate and risedronate), estrogen replacement, selective estrogen receptor modulators (raloxifene), and calcitonin (nasal spray or injection). The FDA has recently approved recombinant hPTH(1-34) (injection), the first approved therapy for stimulating bone formation.

Osteomalacia and Rickets

Osteomalacia and rickets are caused by a mineralization defect during bone formation, resulting in an increase in osteoid, the unmineralized organic matrix of bone.[24] Defective mineralization produces rickets in children and osteomalacia in adults. Osteomalacia or rickets is usually due to either vitamin D deficiency or phosphate depletion.

The causes of decreased 25[OH]D and $1,25(OH)_2D$ are listed in Boxes 49-9 and 49-10, respectively.[245] Vitamin D deficiency may be secondary to dietary deprivation and/or inadequate exposure to sunlight, vitamin D malabsorption, disorders of vitamin D metabolism, or end-organ resistance to the action of vitamin D. In spite of the supplementation of milk, bread, and some cereals with vitamin D, vitamin D insufficiency may be common in the United States.[94,346] Breast-fed infants, the elderly, strict vegetarians, and individuals with darker skin pigmentation are at increased risk. Although clinical osteomalacia caused by vitamin D deficiency appears to be uncommon in the United States, the prevalence of subclinical or mild osteomalacia in the overall population is unknown. Subclinical osteomalacia may coexist with osteoporosis in elderly patients with poor diets and little exposure to sunlight. Vitamin D deficiency may develop in patients with malabsorption caused by postgastrectomy syndrome, small bowel disease (e.g., celiac sprue), hepatobiliary disease, or pancreatic insufficiency.

Vitamin D resistance is rare. Vitamin D–dependent rickets type I is an inherited defect in 25(OH)D-1α-hydroxylase causing impaired formation of $1,25(OH)_2D$. The disease is manifested in infancy and can be treated with physiological doses of $1,25(OH)_2D$. Vitamin D–dependent rickets type II is an inherited disorder characterized by very high serum concentrations of $1,25(OH)_2D$. This syndrome is due to resistance to $1,25(OH)_2D$, secondary to defects in the $1,25(OH)_2D$ receptor.

Osteomalacia and rickets may also occur because of phosphate depletion. The most common cause of rickets in the United States is hypophosphatemic osteomalacia (also known as *hypophosphatemic vitamin D–resistant rickets* and *vitamin D–resistant rickets*).[243] This disorder is an X-linked dominant inherited trait characterized by renal phosphate wasting. Tubular phosphate wasting can also occur sporadically in adults and as part of Fanconi syndrome. Certain rare mesenchymal tumors may also produce a phosphaturic factor (phosphatonin or FGF-23), resulting in renal phosphate wasting and osteomalacia.

Drugs have also been associated with osteomalacia. Anticonvulsants increase the hepatic catabolism of vitamin D metabolites, and produce end-organ resistance. Phosphate-binding antacids used for treatment of peptic ulcer disease cause osteomalacia by preventing the intestinal absorption of phosphate. Etidronate treatment (e.g., of Paget's disease, osteoporosis, or hypercalcemia of malignancy) can cause a mineralization defect and result in osteomalacia.

Clinical manifestations of rickets and osteomalacia are a consequence of the defect in mineralization. Rachitic manifestations include bowing of the extremities, short stature, costochondral-junction swelling, indentation of the lower ribs, and flattening of the skull. In adults, bone pain is the most common symptom, and stress fractures and frank skeletal fractures may occur. X-rays show classic findings in rickets, such as cupping and fraying of the epiphyseal and

diaphyseal ends of the long bone. Pseudofractures are common in adults.

Laboratory findings in rickets and osteomalacia include an increased serum ALP, with other alterations in bone and mineral metabolism dependent on the cause and severity of the disorder. ALP is usually increased because of the increased osteoblastic activity associated with producing unmineralized osteoid. Calcium may be low-normal or low in vitamin D deficiency depending on the severity of the disease. Phosphate may be normal or low, but falls with the development of secondary hyperparathyroidism. The serum calcium and PTH concentrations are usually normal in renal tubular defects of phosphate transport. Vitamin D nutrition may be assessed by the determination of serum 25(OH)D. Renal phosphate defects can be best assessed by determination of the renal phosphate threshold.

Treatment of rickets and osteomalacia is dictated by the etiology of the disorder.[243] Nutritional rickets and osteomalacia are healed by treatment with physiological doses of vitamin D, whereas higher doses may be required in malabsorption. Adequate dietary intakes of calcium and phosphorus are critical during therapy. Renal phosphate-wasting syndromes require frequent, pharmacological administration of oral phosphorus.

Paget's Disease

Paget's disease is a localized disease of bone characterized by osteoclastic bone resorption, followed by replacement of bone in a chaotic fashion.[529] It may affect one or several bones. Paget's disease is common, affecting up to 4% of people older than 40 years. The cause of Paget's disease is unknown, although a viral cause has been suggested by its late onset, spotty involvement, and inclusions that resemble viral nucleocapsids in the nuclei of osteoclasts from patients with Paget's disease. A family history of Paget's disease is reported by 20% to 30% of patients.

The signs and symptoms of Paget's disease depend on which skeletal site is affected; the skull, femur, pelvis, and vertebrae are affected most commonly. In the majority of affected individuals in the United States, the disease is diagnosed from radiographs or laboratory tests (ALP) performed for another reason. In more extensive disease, localized bone pain and increased warmth may occur in or over the affected bone. Advanced disease can produce deformities such as skull enlargement and bowing of the weight-bearing bones (femur and tibia). Complications of deformed bone include arthritic symptoms, nerve compression, deafness, spinal nerve compression and, in rare cases, osteogenic sarcoma.

Laboratory and other findings include increased markers of bone turnover, and abnormal radiographs and bone scans. The most common finding leading to the diagnosis of Paget's disease is increased serum ALP (up to tenfold). Increases in markers of bone resorption (N-telopeptide, deoxypyridinoline, and C-telopeptide) reflect the osteoclastic nature of this disease. Bone markers may be useful in diagnosis and therapeutic monitoring. Radiological examination demonstrates the characteristic findings of Paget's disease: lytic areas in the sites of active osteoclastic bone resorption and thickened, expanded, and sclerotic areas in the site where osteoblasts have formed woven bone. The bone scan is the most sensitive test for detecting small, early lesions.

Therapy is directed at decreasing osteoclastic bone resorption. Bisphosphonates (alendronate, risedronate, pamidronate, and etidronate) and calcitonin are effective in decreasing bone pain, serum ALP, and markers of bone resorption. Patients may occasionally need surgery for skeletal deformity that limits mobility or for arthritic changes, fractures, or nerve compression.

Renal Osteodystrophy

Renal osteodystrophy includes all of the disorders of bone and mineral metabolism associated with chronic renal failure.[113,229,256] The renal bone diseases include both high-turnover bone disease (osteitis fibrosa or secondary hyperparathyroidism) and low-turnover bone disease (osteomalacia and adynamic bone disease). Quantitative histomorphometric analysis of bone biopsies, measurement of bone formation by double tetracycline labeling, and special stains are often necessary to correctly diagnose patients with osteitis fibrosa, osteomalacia, adynamic bone disease, and mixed bone disease of renal osteodystrophy.

Osteitis fibrosa (hyperparathyroid bone disease) is the most common high-turnover bone disease. This disorder is caused by the high concentrations of serum PTH in secondary hyperparathyroidism. Secondary hyperparathyroidism is a consequence of the hypocalcemia associated with hyperphosphatemia and $1,25(OH)_2D$ deficiency. Hyperphosphatemia is a result of the kidneys' inability to excrete phosphate. $1,25(OH)_2D$ deficiency results from the inability of the kidneys to synthesize $1,25(OH)_2$ because of decreased renal mass and suppression of 25(OH)D-1α-hydroxylase activity by high concentrations of phosphate. Deficiency of $1,25(OH)_2D$ leads to reduced intestinal absorption of calcium and reduced inhibition of PTH secretion by $1,25(OH)_2D$. Skeletal resistance to PTH also contributes to the hypocalcemia and secondary hyperparathyroidism.

Low-turnover bone diseases include osteomalacia and adynamic (also known as aplastic) bone diseases. Osteomalacia and adynamic bone disease are distinguished by the extent of unmineralized bone matrix or osteoid: osteoid is increased in osteomalacia and normal or low in adynamic bone disease. Osteomalacia in chronic renal failure may reflect vitamin D deficiency because of the decreased renal synthesis of $1,25(OH)_2D$ (see Osteomalacia and Rickets) or aluminum-related disease. In the 1970s and 1980s, aluminum intoxication was a significant contributing factor to the development of osteomalacia and adynamic bone

disease. Aluminum intoxication was commonly caused by aluminum contamination of dialysis water and by the therapeutic use of oral aluminum-containing antacids to reduce serum phosphate by binding phosphate and preventing its intestinal absorption. The inability of patients with renal failure to excrete aluminum leads to high concentrations in serum (see Chapter 35) and deposition in bone, inhibiting bone cell function and bone mineralization. Aluminum-related disease is less common today because of the reduced use of aluminum-containing antacids and the use of effective means to decrease the concentrations of aluminum in dialysis water. Other causes of adynamic renal bone disease include calcium supplementation, excessive vitamin D administration, treatment of hyperparathyroidism, advanced age and osteoporosis, diabetes, corticosteroid therapy, and immobilization. Today, oversuppression of parathyroid function (produced by the use of oral calcium carbonate to control hyperphosphatemia and treatment with vitamin D and dialysate solutions containing high calcium to control hyperparathyroidism) is believed to be the main cause of adynamic renal bone disease.

Amyloid deposition may be noted in bone and in other tissues. It is thought to result from the reduced degradation of β_2-microglobulin by the kidneys. The amyloid in renal failure is primarily composed of β_2-microglobulin. The fraction of patients with amyloidosis increases with the duration of dialysis therapy; 70% to 80% of patients have clinical features of amyloidosis after 10 or more years of hemodialysis. Amyloidosis may coexist with either high-turnover or low-turnover bone disease.

Bone pain is the most common complaint of patients with renal osteodystrophy. The weight-bearing bones are the site of most discomfort, with leg and hip pain and back pain being common. If the patient is a growing child, skeletal deformities may result, with bowing of the extremities, kyphoscoliosis, and slipped femoral epiphyses. Extracellular calcification is also commonly found in the periarticular areas, in the medial layer of arteries, and as calcification of internal organs (lungs, heart muscle, and other tissue).

Biochemical findings in chronic renal failure may include hyperphosphatemia and hypocalcemia. PTH may be increased and $1,25(OH)_2D$ decreased. Serum ALP is increased in patients with either hyperparathyroidism or osteomalacia. Because magnesium is cleared by the kidney, modest elevations (2 to 4 mg/dL) are common, especially in those taking magnesium-containing antacids.

Early management of renal failure calls for dietary restriction of phosphate and administration of phosphate-binding agents. Calcium supplements added to the diet to prevent secondary hyperparathyroidism may also serve as phosphate binders. Administration of $1,25(OH)_2D$ or other active forms of vitamin D enhances intestinal calcium absorption and may also act directly on the parathyroid gland to reduce PTH secretion. Ultimately, dialysis or renal transplantation may be necessary.

TABLE 49-5 Markers of Bone Resorption

Marker	Method
Telopeptides	
N-telopeptide (NTx)	ELISA, ICMA

BIOCHEMICAL MARKERS OF BONE TURNOVER

The development of methods to measure serum and urinary markers of bone turnover has been stimulated by a greater understanding of bone metabolism, increasing awareness of bone diseases—particularly osteoporosis—and the approval of new drugs for treating osteoporosis and other metabolic bone diseases.* Biochemical markers of bone turnover can be separated into markers of bone resorption (Table 49-5), which are produced by osteoclasts during bone resorption, and markers of bone formation, which are produced by osteoblasts during bone formation (Box 49-13).

More recently, methods have been developed for the measurement of osteoprotegerin and RANK ligand, proteins synthesized by the osteoblast and influencing osteoclast formation, activation, and bone resorption. Additional studies are required to determine the roles of RANK ligand and osteoprotegerin as markers of bone turnover.[255,557]

Selection and interpretation of biochemical markers of bone resorption and formation, for osteoporosis and other metabolic diseases, are complicated by preanalytical, analytical, and postanalytical considerations. Bone markers measure the overall rate of bone resorption or formation.

*References 3, 97, 106, 149, 208, 209, 236, 282, 291, 300, 313, 345, 397, 511, 512, 514, 610.

They cannot identify the type of bone or the location of the bone with the altered formation or resorption. In bone disorders in which bone resorption and formation are coupled and dramatically altered, either class of marker will identify changes in bone turnover.

Biochemical markers of bone resorption and formation have a number of potential uses* including (1) monitoring the effectiveness of therapy, (2) selection of patients for therapy, (3) prediction of bone loss, and (4) prediction of fracture risk. Of these, bone markers are currently most used for monitoring the effectiveness of therapy. Effective antiresorptive therapy is followed by a significant reduction in resorption markers within few weeks, normally reaching a plateau within 3 to 6 months. Markers of bone formation respond more slowly, usually reaching a plateau at 6 to 12 months. Depending on the antiresorptive therapy and the bone marker, effective therapy is associated with a bone marker reduction of 20% to 80%.

In contrast to many bone diseases, osteoporosis is often characterized by modest alterations in bone turnover, and thus only small changes may occur during therapy. A period of 1 to 3 years must pass before measurements of bone mass (for example, dual energy x-ray absorptiometry) can identify statistically significant changes in bone mass during therapy. Measurements of bone markers provide earlier assessments of bone resorption and/or formation. Because most current therapies are antiresorptive and resorption markers respond more quickly to these therapies, resorption markers have received the greatest attention.

In addition to their use in metabolic bone disease, markers of bone turnover are potentially useful tools in diagnosing and monitoring metastatic bone disease.[2,117,149,190] As with metabolic bone disease, there is more evidence supporting the use of resorption markers in monitoring therapy. Additional studies are required to determine the ultimate clinical utility of bone markers in metastatic bone disease.

Preanalytical and Analytical Variables

Preanalytical and analytical variables significantly reduce the usefulness of measurements of markers of bone formation and resorption. The long-term, within-individual variability of urine markers is generally higher (15% to 60%) than that of serum markers (5% to 10%).[31,218,345,550,586]

Bone marker concentrations in urine and serum vary with the time of day because of the diurnal variation of bone resorption and formation.[58,160,161,505] Because of the nocturnal peak in bone turnover, most bone markers peak in the early morning hours (4 AM to 8 AM) and reach their nadir in the afternoon (1 PM to 11 PM). The amplitude of this variation is greatest for resorption markers, with nadir values averaging 70% of peak values. Consequently, specimens should be collected at a specific time of day to minimize the impact of diurnal variability on between-specimen comparisons. For urinary markers, collection of the second morning void is often recommended. Compared with other bone markers, BAP does not demonstrate much diurnal variation because of its long half-life in serum.

Concentrations of urinary resorption markers are usually normalized by dividing by the urinary creatinine concentration. The variability (within- and between-method) of creatinine measurements, within-subject variability in urinary creatinine, and creatinine's dependence on muscle mass contribute to the overall variability of urinary resorption markers.

Markers of Bone Resorption

Bone resorption markers are listed in Box 49-5. N- and C-telopeptides of type I collagen (NTx and CTx) and deoxypyridinoline are most frequently measured. Other markers include serum tartrate-resistant acid phosphatase (TRAP) and hydroxyproline. Bone resorption markers, apart from TRAP, were initially measured in urine. More recently, methods using serum have been developed for a number of these analytes including N- and C-telopeptides.

Telopeptides and Pyridinium (Deoxypyridinoline and Pyridinoline) Cross-Links

Type I collagen accounts for approximately 90% of the organic matrix of bone. Type I collagen, a triple helix of two identical α-1(I) chains and a slightly different α-2(I) chain, is synthesized as a precursor, type I procollagen, containing both N- and C-terminal extensions.[482]

Each chain contains approximately 1000 amino acids and has a molecular weight of approximately 140,000. Procollagen undergoes extensive intracellular posttranslational processing, including hydroxylation of proline and lysine residues, glycosylation, and formation of intrachain and interchain disulfide bonds and the triple helix. After it is secreted, procollagen is converted to collagen during extracellular processing with the enzymatic removal of N- and C-terminal propeptides (procollagen peptides).

Type I collagen molecules spontaneously assemble into immature fibrils with limited tensile strength, then mature by the formation of intramolecular and intermolecular covalent bonds or cross-links.[473] Lysyl oxidase deaminates the ε-amino group of specific lysines or hydroxylysines to produce active aldehydes. Three amino acid side chains react to form a trivalent amino acid containing the 3-hydroxypyridinium ring. The following two nonreducible cross-links have been identified.

1. Deoxypyridinoline (lysyl pyridinoline) formed by the reaction of two hydroxylysine side chains and one lysine side chain
2. Pyridinoline (hydroxylysyl pyridinoline) formed by the reaction of three hydroxylysine side chains

These prominent pyridinium cross-links stabilize mature collagen chains within the extracellular matrix in fibrous

*References 141, 143, 144, 208, 209, 303, 379, 453, 538, 610.

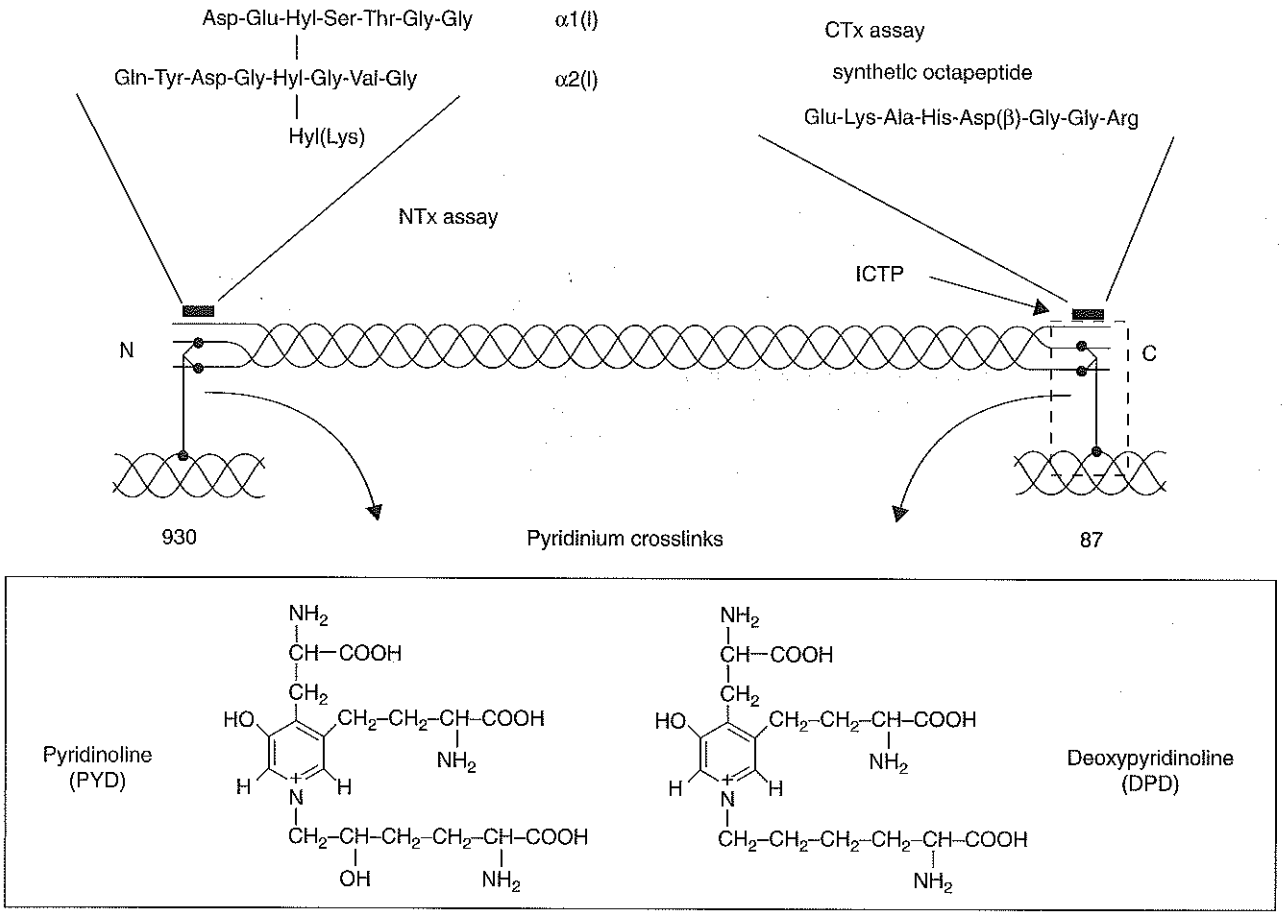

Figure 49-24 Pyridinium cross-links and N-telopeptides of type I collagen. Cross-links occur at two intermolecular sites in the collagen fibril: (1) two N-telopeptides are linked to a helical site at residue 930, and (2) two C-telopeptides are linked to helical residue 87. The location and amino acid sequence of the N-telopeptide (NTx) and the C-telopeptide (CTx) and the structures of the free pyridinium cross-links (pyridinoline and deoxypyridinoline) are shown. *ICTP,* C-terminal telopeptide of type I collagen. *(From Robins SP. Biochemical markers of bone metabolism. CPD Bulletin Clin Biochem 1999;1:116-21.)*

collagen and most mature connective tissues, with the notable exception of skin.

Intermolecular cross-linking sites have been located that form the pyridinium cross-links in type I collagen (Figure 49-24). Two N-telopeptide sites are linked to the helical site at amino acid 930 (N-telopeptide) or two C-telopeptides are linked to the helical site amino acid 87 (C-telopeptide).

Deoxypyridinoline (DPD) (Figure 49-24) is a more sensitive and specific marker of bone resorption than pyridinoline (PYD):* DPD is found in significant quantities only in bone, dentine, ligaments, and aorta, whereas PYD is more widespread, occurring in hard connective tissues with high levels in cartilage. Because of the large mass of the skeletal system, bone is usually the major source for both PYD and DPD. Neither substance is present in significant quantities in skin.

*References 35, 97, 177, 180, 206, 282.

DPD is a sensitive and specific marker of bone resorption because:

1. It is formed during collagen maturation, not biosynthesis, and originates only as a breakdown product of mature matrix.
2. It does not appear to be metabolized before excretion in urine.
3. Bone is the major source of DPD.
4. It does not appear to be absorbed from the diet.

Pyridinium cross-links (DPD and PYD) and telopeptides containing these cross-links are released into the circulation by hydrolysis of type I collagen during bone resorption and excreted in urine.

Clinical Significance of Telopeptides and Deoxypyridinoline

Elevated concentrations of telopeptides and DPD have been reported in osteoporosis, Paget's disease, metastatic bone disease, primary and secondary hyperparathyroidism, hyperthyroidism, and other diseases with increased bone

resorption.* When postmenopausal women are compared with premenopausal controls, telopeptides are usually increased more than other markers of resorption and formation.[163,211,213,441]

Inhibition of bone resorption with pharmacological agents leads to a decrease in telopeptides and DPD. Treatment of postmenopausal women or osteoporotics with bisphosphonates or estrogen replacement therapy decreases bone resorption markers. Although markers of bone formation are also decreased because of coupling, reductions are delayed and not as great as those observed for markers of bone resorption. Response to antiresorptive therapy is generally greatest with telopeptides, intermediate with total DPD, and lowest with free DPD.[210,292]

In patients with Paget's disease treated with bisphosphonates, N-telopeptide was suppressed more than total or free DPD or hydroxyproline and best predicted the outcome of therapy.[15,50,210,425]

Measurement of Telopeptides and Pyridinium Cross-Links

NTx, CTx, and DPD are most frequently used to measure bone resorption. Methods are commercially available for the measurement of NTx and CTx in serum and urine and deoxypyridinoline in urine (see Table 49-5).

N-Telopeptide. NTx in urine is measured with a commercially available ELISA. It uses a monoclonal antibody against the NTx fraction of normal adolescent urine.[241] The antibody recognizes a conformational epitope of the cross-linked α_2(I)N-telopeptide containing the sequence QYDGKGVG, which is a product of osteoclastic proteolysis. It does not recognize a precursor that is not cross-linked, but does measure other types of cross-links (pyrrolic). Its freedom from cross-reactivity with precursors that are not cross-linked ensures that only collagen degradation is measured. Measurement of NTx may provide increased specificity for bone because DPD cross-links involve primarily the α_2(I) chain, whereas the α_1(I) predominates in other tissue, and two thirds of the DPD cross-links in bone collagen are at the NTx site, whereas one third are at the CTx site. In this assay, microtiter plates are coated with a urinary peptide conjugate. Samples or calibrators are added, followed by the NTx monoclonal antibody. After incubation and washing, bound antibody is quantified by adding goat antimouse IgG conjugated to horseradish peroxidase. A modification of this method is also available on an automated immunoassay analyzer using an EIA with chemiluminescence detection.

More recently, this method has been adapted for the measurement of NTx in serum.[109,217] The use of serum eliminates the need to measure urine creatinine to correct for urine concentration and significantly reduces the within-subject day-to-day variation in NTx measurements.

*References 15, 50, 52, 97, 145, 441, 472, 477, 513, 582, 583.

C-Telopeptide. Unlike the NTx assay, which used the NTx from adolescent urine as the immunogen, CTx immunoassays used an antibody against a synthetic fragment of the CTx corresponding to residues 15C to 22C (EKAHDGGR) of the α_1(I) chain of type I collagen.[61] This region includes the cross-linking hydroxylysine at residue 16C. Several methods have been developed for measuring CTx in urine and serum. The most widely used methods recognize the β-isomer, formed during aging of bone by the transfer of the peptide backbone from the α-carboxyl group to the β-carboxyl group. This ensures that the measured CTx is from mature collagen, not precursors, and reflects bone resorption. All methods require the C-terminal amino acid to be a free arginine (R). CTx is measured in urine with an ELISA using a polyclonal rabbit antibody. Microtiter plates are coated with the synthetic peptide, followed by incubation with samples or calibrators and rabbit antibody against the 8–amino acid synthetic fragment. After washing, bound antibody is quantified by addition of peroxidase-conjugated goat antirabbit IgG. CTx is measured in serum using two monoclonal murine antibodies.[60,429,479] With two α_1(I) chain telopeptides in each collagen molecule, the use of two antibodies directed against the β-isomer ensures that only the β/β forms are measured. A modification of this method is now available on an automated immunoassay analyzer using electrochemiluminescence detection.[204]

Another group of investigators has reported an RIA for the C-terminal telopeptide of type I collagen (ICTP) in serum.[467] Rabbit antibodies were raised against a cross-linked C-telopeptide of type I collagen produced by collagenase digestion of human bone. This method is relatively insensitive to changes in bone resorption in osteoporosis, but does detect increases in myeloma and metastatic bone disease. This appears to be because of the metabolism of the epitope recognized by this assay by cathepsin K, an enzyme likely to be responsible for collagen resorption in osteoporosis.

Pyridinium Cross-links (Deoxypyridinoline and Pyridinoline). DPD and PYD were originally measured by HPLC (see Table 49-5). Today, DPD is measured primarily by immunoassay using automated analyzers (EIA with chemiluminescence detection and ICMA) or manual ELISA. Unlike most HPLC methods, which measure total DPD and total PYD, the immunoassays for DPD or DPD/PYD measure primarily free but not peptide-bound forms. In urine, approximately 40% of the PYD and DPD is free and 60% is protein-bound.

Comparisons of free and total DPD and PYD suggest that the ratio of free to total pyridinolines varies with physiology, pathophysiology, and treatment.[163,210,292] Total DPD has been reported to be increased more than free DPD in individuals with disorders involving increased bone resorption (postmenopausal women, osteoporosis, Paget's disease, and hyperthyroidism). Furthermore, short-term bisphosphonate treatment of patients with Paget's disease or osteoporosis

reduced the total, but not the free, DPD, whereas estrogen treatment of postmenopausal women decreased both.

Immunoassays. A number of immunoassays[97,206,282] have been developed to measure DPD and PYD. One commercially available ELISA measures both PYD and DPD with equimolar cross-reactivity.[225,520] Of greater interest for monitoring bone resorption is the commercially available ELISA that measures DPD but not PYD.[475] This method, a competitive ELISA, uses a streptavidin-coated microtiter plate and biotinylated deoxypyridinoline as the solid phase. Sample or calibrator and the monoclonal antibody against DPD are added and incubated. After washing, a second antibody, goat antimouse IgG conjugated to ALP, is added. Bound antibody-antibody-enzyme conjugate is measured after addition of *p*-nitrophenyl phosphate.

More recently, automated immunoanalyzer methods for DPD have become commercially available. The most widely used is a solid-phase, competitive EIA with chemiluminescence detection. The solid-phase antibody is incubated with serum or calibrator and ALP conjugated to DPD. After washing, the antibody-antigen-enzyme complexes are determined after the addition of substrate.

High-Performance Liquid Chromatography. DPD and PYD can be measured by HPLC with fluorescence detection.* Because about 60% of the pyridinolines in urine are contained in peptides, most methods use acid hydrolysis to generate free amino acids. The hydrolysate is fractionated by column chromatography on cellulose CF-1 before resolution of the pyridinolines by reversed-phase chromatography. Because the pyridinolines are highly polar at acid pH, ion-pairing agents have been used to increase their retention by reversed-phase columns. Although most methods have used gradient elution, simpler isocratic methods have been described.[281,334] Fluorometric detection is used to quantify these naturally occurring fluorescent pyridinium compounds. The lack of synthetic calibrators, controversy over the molar fluorescence yield of pyridinolines, and the variability of acid hydrolysis have been suggested as factors contributing to the differences observed between laboratories.[178,474]

Specimen Requirements. DPD and telopeptides are relatively stable in urine.[48,215] Exposure to UV light, but not laboratory lighting, decreased DPD and PYD. Free pyridinolines were especially vulnerable to UV lighting. It is recommended that prolonged exposure to light and exposure to direct sunlight be avoided.

Peak urinary excretion of pyridinolines occurs at about 5 AM to 8 AM, reflecting the nocturnal peak in bone turnover. Urinary pyridinolines reach a nadir between 2 PM and 11 PM.[58,160,161,505]

Both timed and random urine tests have been used for pyridinolines and telopeptides. Although early studies used 24-hour urine samples, timed or early-morning voided urine have also been used. A second-morning void, collected by 10 AM, is most commonly recommended. For monitoring, specimens should be collected at the same time as the baseline specimen.

Within-subject biological variation of bone markers has been reported to be (coefficients of variation) 5% to 60%.[31,218,550,586]

Reference Intervals. Appropriate reference intervals for telopeptides and DPD depend on the reason for ordering the test. For osteoporotic women, results are usually compared with those for healthy premenopausal women. Representative reference intervals for NTx, CTx, and DPD are listed below[614A]:

Test	Premenopausal Women	Men
N-telopeptide		
Serum, nmol BCE/L	8.7-19.8	10.7-22.9
Urine, μmol BCE/mol creatinine	10-110	11-103
C-telopeptide		
Serum,* ng/L	≤573	≤584
Urine (mg/mol creatinine)	220 (128)†	249 (128)†
Deoxypyridinoline, Free (μmol/mol creatinine)	3.0-7.4	2.3-5.4

*CTx by automated immunoassay with electrochemiluminescence detection
†Mean (SD)

Concentrations of collagen cross-links are influenced by age and gender. Concentrations are markedly higher in children, with the highest concentrations observed during early infancy and adolescence, periods of rapid bone growth. In adults, concentrations of collagen cross-links are relatively constant between the ages of 30 and 45, but increase significantly after menopause in women. For women, adult reference intervals are usually based on normally cycling premenopausal women (with normal menstrual cycle and normal follicle-stimulating hormone), 30 to 45 years of age. Age-related increases have also been reported in men.

Tartrate-Resistant Acid Phosphatase

During bone resorption, osteoclasts produce and secrete an acid phosphatase. The activity of this TRAP has been measured using a number of methods. Unfortunately, most methods failed to distinguish between the osteclastic TRAP (isoform 5b) and other TRAPs (isoform 5a) found in plasma.[443] In addition, instability of the enzyme and association of the enzyme with α_2-macroglulin have complicated

*References 44, 97, 177, 179, 206, 282, 583.

the development of methods. Immunoassays have also been developed for measuring TRAP using antibodies raised against TRAP obtained from spleen cells of patients with hairy cell leukemia, human cord plasma, and recombinant TRAP.[105,312,443] More recently, two approaches have been used to measure TRAP 5b: (1) a kinetic method measuring enzyme activity of TRAP 5b using fluoride inhibition of TRAP 5b and heparin inhibition of TRAP 5a,[394] and (2) an immunoassay using monoclonal antibody for TRAP 5b.[239,240] Although the initial investigations of these new methods for TRAP 5b are encouraging, limited data are currently available regarding the clinical performance of these methods.

Urinary Hydroxyproline

Hydroxyproline is found mainly in collagens, where it accounts for about 13% of the total amino acid content and is derived from proline by posttranslational hydroxylation.[35,140,175,470] About 10% of hydroxyproline released during collagen catabolism is excreted in urine, mainly as small dialyzable peptides. Although assays have been reported for free hydroxyproline and hydroxyproline in dialyzable and nondialyzable peptides in urine and serum, methods for total urinary hydroxyproline have been more commonly used.[140,175,470,581,607] Hydroxyproline is released from peptides by acid hydrolysis. Early photometric assays involved oxidation of hydroxyproline to pyrrole, followed by reaction with Ehrlich's reagent (4-dimethylaminobenzaldehyde).[34,302,445] Ion-exchange chromatography before analysis and other modifications have been advocated to reduce interference by urinary components and improve assay specificity.[231] Sensitive and specific reversed-phase HPLC methods have been described. They use photometric or fluorometric precolumn derivatizing agents, including dabsyl and dansyl chloride, phenylisothiocyanate, *o*-phthalaldehyde, 4-chloro-7-nitrobenzofurazan, 9-fluorenylmethyl chloroformate, and *N,N*-diethyl-2,4-dinitro-5-fluoroaniline.[133,426,455]

Urinary hydroxyproline is not specific for either bone turnover or bone resorption for a number of reasons, including: (1) other tissues, including muscle and skin, and the C1q fraction of complement contain a significant proportion of the body's collagen[140]; (2) a significant percentage of collagen is degraded during synthesis and maturation, including N-terminal and C-terminal propeptides (procollagen peptides); and (3) its concentration is altered by various diseases and other factors, including diet. With the availability of more sensitive and specific markers of bone resorption, hydroxyproline is not routinely used to assess bone turnover or bone resorption.[97,206]

Markers of Bone Formation

Bone formation markers are listed in Box 49-13. BAP and osteocalcin are most frequently measured. Procollagen peptides are less frequently measured. Bone formation markers are measured in serum or plasma.

Bone Alkaline Phosphatase

ALP is found in many tissues, including bone, liver, intestine, kidney, and placenta (see Chapter 21). Four different genes code for the tissue-nonspecific, intestinal, placental, and germ-cell (placental-like) isoenzymes.[97,244,442] The ALPs from liver, bone, and kidney are isoforms of the same gene product, the tissue-nonspecific gene. These tissue-specific isoforms are produced by tissue-specific posttranslational processing (e.g., glycosylation) of the gene product.

ALP determined by usual biochemical panels reflects total serum concentrations and does not distinguish the source of the isoenzyme (i.e., liver, bone, or some other source). Clinicians must therefore rely on other markers of liver or other organ function or a more tissue-specific determination of ALP to assess the source of ALP. In normal individuals, ALP originates primarily from liver and bone. The bone isoenzyme is the marker of bone formation and is found in osteoblasts.

Clinical Significance

BAP is increased in metabolic bone diseases, including osteoporosis, osteomalacia and rickets, hyperparathyroidism, renal osteodystrophy, and thyrotoxicosis, and in individuals with acromegaly, bony metastases, glucocorticoid excess, Paget's disease, and other disorders with increased bone formation.*

The measurement of BAP has several advantages over osteocalcin measurement. Because of its relatively long half-life in vivo (1 to 3 days), it is relatively unaffected by diurnal variation. BAP is more stable in vitro and does not require special specimen handling. BAP is more useful in individuals with impaired renal function because it is not cleared by glomerular filtration.

Of current biochemical markers, total ALP or BAP provides the highest clinical sensitivity and specificity in the diagnosis and monitoring of Paget's disease.[15] Although total ALP is most often used, BAP is more sensitive than total ALP in mild Paget's disease. Osteocalcin is relatively insensitive and less useful than BAP in Paget's disease. Total ALP is not useful in metabolic bone diseases with mild elevations of BAP.

Measurement of BAP may be misleading in patients with liver disease, severe osteomalacia, or increased concentrations of $1,25(OH)_2D$. BAP may be misleading in liver disease because of the cross-reactivity of current methods with liver ALP. In severe osteomalacia, BAP may be markedly increased without an increase in bone mineralization because of a mineralizing defect.[553] Because 1,25-dihydroxyvitamin D regulates the synthesis of BAP and osteocalcin, both of these markers may be misleading in patients treated with calcitriol and in patients with abnormal concentrations of this hormone.

*References 97, 106, 136, 236, 289, 316, 345, 397, 512, 514.

Measurement of Bone Alkaline Phosphatase

BAP measurement methods have used heat inactivation, chemical inhibition, electrophoresis, isoelectric focusing, lectin precipitation and chromatography, HPLC, and other approaches, singly and in combination. Conventional electrophoresis provides qualitative, not quantitative, detection because of the overlapping migration of isoforms and isoenzymes. Heat inactivation and chemical inhibition with urea, l-phenylalanine, l-homoarginine, or levamisole have been used with some success. Internal standards of ALP isoenzymes have been used to increase assay precision.[182,184]

Wheat germ agglutinin (WGA), a lectin, has been used to measure BAP by affinity chromatography, affinity electrophoresis, or differential precipitation of isoforms.[17,84,228,371] Some methods have used a combination of techniques to improve specificity. These classic measurements for BAP are usually technically complicated and labor-intensive, imprecise, insensitive, and inaccurate. Of these techniques, heat denaturation and WGA precipitation have been used most frequently. Heat denaturation has been criticized because of its irreproducibility or variability.[305] WGA precipitation has been criticized because WGA does not precipitate all BAP from pagetic sera or from the SaOS-2 osteosarcoma cell line and fails to completely separate bone and liver activity.[305]

Several immunoassays have been reported for BAP.* Two immunoassays are commercially available; both use monoclonal antibodies against BAP from SaOS-2 cells. One immunoassay is an IRMA using two monoclonal antibodies, a capture antibody and a radioiodinated signal antibody, reacting preferentially with BAP.[79,205,253,254,316] This two-site immunoassay measures the mass of BAP in ng/mL (μg/L). Subsequently an immunoenzymatic method was developed by replacing the signal antibody with the direct measurement of the activity of immobilized BAP.[79] A modification of this method is available on an automated immunoassay analyzer using a chemiluminescent assay. The other assay uses a single monoclonal antibody against BAP.[181,226] Microtiter plates are coated with this antibody and used to separate BAP from other isoforms and isoenzymes. After immunoseparation, the activity (U/L) of BAP is determined with a *p*-nitrophenyl phosphate substrate.

The analytical and clinical performance of these BAP immunoassays have been characterized in a series of articles.† Unfortunately, current immunoassays are not completely specific for BAP and exhibit 7% to 17% cross-reactivity with ALP from liver.[79,444] It has been difficult to exactly determine cross-reactivity for the liver isoform because of limitations of existing preparations and an incomplete understanding of the exact nature of the circulating isoforms. BAP immunoassays provide greater sensitivity and specificity for bone formation than does the measurement of total ALP. Current methods for BAP are not reliable in patients with liver disease with increased concentrations of the liver isoform.

Figure 49-25 Amino acid sequence of osteocalcin. A disulfide bond formed between cysteines in positions 23 and 29 stabilizes two antiparallel α-helical structures representing 40% of the overall structure. Three glutamyl residues at positions 17, 21, and 24 can be carboxylated in a posttranslational, vitamin K–dependent, enzymatic step producing γ-carboxyglutamyl (Gla) residues.

Reference Intervals

Normal concentrations of BAP are approximately 5 to 20 ng/mL (μg/L) with the IRMA[205,423,609,611] and 11.6 to 29.6 and 15.0 to 41.3 U/L for premenopausal women and men, respectively, with the immunoabsorption assay.[226,609,611] For the automated chemiluminescent immunoenzymatic method, the 95th percentile limit is reported to be 14.3 and 20.1 ng/mL for premenopausal women and men, respectively. Serum concentrations of BAP are influenced by age and gender. Concentrations are higher in men and increase with age in both men and women, consistent with the age-related increase in bone turnover. Children have much higher concentrations, especially during growth spurts.

Osteocalcin

Osteocalcin (OC) is the major and most thoroughly characterized noncollagenous protein in human bone (Figure 49-25).* This protein, previously referred to as bone Gla protein (BGP), accounts for approximately 1% of the total protein in human bone. It is a small protein of 49 amino acids with a molecular weight of 5669.

OC is considered to be a marker of bone formation because during bone formation 10% to 30% of the OC synthesized by osteoblasts is released into the circulation. However, OC, especially OC fragments, may also be liberated during bone resorption and measured by some

*References 97, 208, 236, 237, 327, 333, 440, 512, 514.

methods. Its synthesis is stimulated by $1,25(OH)_2D$. OC is cleared by the kidneys. The half-life of circulating OC is approximately 5 minutes.

OC contains three specific glutamyl residues at amino acid positions 17, 21, and 24, which may be converted to γ-carboxyglutamyl residues by a posttranslational, vitamin K–dependent enzymatic carboxylation. This unique carboxylated amino acid binds calcium ions and is found in various proteins involved in blood coagulation and in calcium transport, deposition, and homeostasis. Undercarboxylated OC, which has been reported in serum in some conditions, may be related to decreased bone density and may respond to administration of vitamin K. Although OC binds calcium and hydroxyapatite, its physiological role is unknown.

Immunochemical and chromatographic studies have demonstrated considerable heterogeneity for circulating OC in normal individuals and patients with osteoporosis, chronic renal failure, and Paget's disease.* This heterogeneity may be a result of proteolytic hydrolysis of susceptible peptide bonds involving arginine residues at positions 19-20 and 43-44. Peptides containing amino acids 1-19, 20-43, 45-49, 1-43, and 20-49 can be produced by hydrolysis of one or two of these bonds.

Sequence-specific competitive and noncompetitive immunoassays have been developed and used to measure OC and fragments of OC.[212] Intact OC accounts for about 35% of immunoreactivity in normal subjects, 45% in patients with osteoporosis, and 25% in patients with chronic renal failure (CRF). The N-terminal/midregion fragment, possibly 1-43, accounted for 30% of immunoreactivity in normal subjects and osteoporotics and 50% in patients with CRF. Other fragments were present at considerably lower concentrations than 1-43. All specimens were collected in tubes containing agar-agar, placed on ice, promptly separated, and frozen at −80 °C to minimize proteolysis.

Intact OC appears to be rapidly hydrolyzed when serum is incubated at room temperature, and more slowly at 4 °C.[49,212] At room temperature, immunoreactivity measured with the intact assay had declined by about 20% at 3 hours, whereas immunoreactivity with the assay measuring both intact hormone and the 1-43 fragment was unchanged. This N-terminal/midregion fragment may be released by osteoblasts during bone formation and produced in vivo in the circulation and in vitro during specimen handling by proteolysis of intact OC.

Clinical Significance

OC is increased in metabolic bone diseases with increased bone or osteoid formation, including osteoporosis, osteomalacia and rickets, hyperparathyroidism, renal osteodystrophy, and thyrotoxicosis, and in individuals with fractures, acromegaly, and bony metastases.* OC is decreased in hypoparathyroidism, hypothyroidism and growth hormone deficiency, and during estrogen replacement therapy and treatment with glucocorticoids, bisphosphonates, and calcitonin.

OC concentrations may be misleading in several situations.[553] Concentrations may be increased in patients with impaired renal function without an increase in bone formation, since OC is cleared by the kidneys. OC may increase during bed rest without an increase in bone formation. Serum OC may not reflect bone formation in patients treated with $1,25(OH)_2D$ or those with abnormalities in this hormone since OC is regulated by $1,25(OH)_2D$.

Measurement of Osteocalcin

Many different immunoassays have been developed for OC since the first assay was reported in 1980.† The first immunoassays for human OC were competitive RIAs using bovine OC as immunogen and radioiodinated tracer. Because of the complete homology between amino acids 20 to 49 of bovine and human OC, the majority of antisera were directed against the C-terminal of OC. Consequently, these methods measured both intact OC and OC fragments containing the C-terminal region. Others developed antisera against ovine OC, with its complete homology with human OC between amino acids 11 and 49,[427] purified intact human OC,[552] or synthetic fragments of human OC.[101] Competitive immunoassays have also used enzyme[439,440,478,576] and chemiluminescent[295] labels. Monoclonal antibodies against bovine and human OC have also been used in competitive immunoassays.[439,440,576]

More recently, noncompetitive methods have been developed for measuring human OC. These immunoassays use monoclonal antibodies and affinity-purified polyclonal antisera against synthetic peptides of human OC or intact human or bovine OC.‡ Many antibody pairs have been reported including capture [and signal] antibodies, respectively, against amino acid sequences 12-33 [and 34-49], 43-49 [and 5-13], 25-37 [and 5-13], 20-43 [and 7-19], 1-19 [and 20-49], and 1-12 [and 15-30 or 38-49]. These noncompetitive methods have used signal antibodies labeled with radioactivity (IRMA), enzymes (EIA/ELISA), or chemiluminescent compounds (ICMA).

Noncompetitive methods measuring intact OC and especially those measuring both intact OC plus the N-terminal/midregion (1-43) fragment are of particular interest.[49,212,480] These assays do not measure smaller fragments of OC, which is an advantage, since fragments might be produced during bone resorption. OC concentrations are more stable when measured with assays recognizing both

*References 97, 206, 212, 327, 333, 440, 512, 514, 576.

*References 97, 206, 236, 333, 395, 440, 470, 512, 514.

†References 64, 97, 236, 327, 333, 440, 512, 514, 576.

‡References 49, 97, 138, 152, 271, 369, 382, 440, 480.

intact hormone (1-49) and the N-terminal/midregion (1-43) since this fragment is produced in vitro by hydrolysis of intact OC.

The circulating concentration of OC measured in normal subjects varies widely among methods and laboratories.[97,152,369,440,576] One study reported that *mean* values for normal individuals ranged from 3 to 27 ng/mL (μg/L). This variability may be a consequence of differences in antisera specificity and sensitivity, and in the purity, potency, and immunoreactivity of OC calibrators.[142] Another important source of variation between methods may be their dependence on or independence of calcium concentration in the assay.[576] Calcium binding to γ-carboxyglutamyl residues induces a conformational change in OC. Although EDTA is added to some assays to eliminate this effect, other assays require the addition of calcium.

Antiserum specificity and the heterogeneity of circulating OC are probably the primary reasons for differences observed between methods.[49,212] Depending on antiserum specificity, methods may measure intact OC or fragments containing the N-terminal, C-terminal, or midregion amino acids or some combination of these forms. These fragments may be produced during bone formation or resorption, in the circulation, or in vitro during preanalytical handling. The development of two-site methods and greater knowledge of OC metabolism should provide a basis for greater standardization of these measurements.

Specimen Requirements

Serum is the most widely used specimen for the measurement of OC; heparinized plasma can be used with some methods. The stability of OC in samples is method-dependent. Decreases in OC immunoreactivity of 50% to 70% after 6 to 24 hours at room temperature and 40% to 80% after 2 weeks at 4 °C have been reported.[26,49,212] Trasylol,[26] mixed protease inhibitors,[212] and collection on ice[49,212] improve the stability of OC with some but not all methods. Serum OC concentrations are more stable with methods measuring both intact OC and the N-terminal/midregion fragment (1-43). Concentrations were unchanged after 3 hours at room temperature and after 24 hours at 4 °C.[49,212]

Specimen stability should be determined and collection and handling optimized for each method. Unless proven unnecessary, specimens should be collected on ice, separated within 1 hour, and immediately frozen. Freeze-thaw cycles should be avoided. The use of EDTA plasma and/or protease inhibitors should be evaluated.

Reference Intervals

Methods for OC are not harmonized as illustrated by the reference intervals listed below[614A]:

	ng/mL (μg/L)
IRMA	
Children	
6-9.9 y	40.2-108
10-13.9 y	35.8-166
14-17.9 y	
Males	27.8-194
Females	16.3-68.7
Adult male	11.3-35.4
Adult female	7.2-27.9
ICMA	
Adult male	1.1-7.2
Adult female	
Premenopausal	0.5-7.0

OC concentrations are influenced by age, gender, and diurnal variation.[97,333,440,470] Concentrations are higher in children, with the highest concentrations observed during periods of rapid growth. Males have somewhat higher concentrations of OC. OC concentrations have been reported to increase, decrease, or remain unchanged with advancing age, a probable consequence of the heterogeneity of circulating OC and differences in immunoassay specificity. OC concentrations are generally increased during menopause. OC exhibits a diurnal variation with a nocturnal peak, dropping by as much as 50% to a morning nadir. OC concentrations are increased in individuals with renal failure.

Procollagen Peptides (Collagen Propeptides)

Type I collagen is synthesized as a precursor, procollagen, containing both N- and C-terminal extensions.* These extensions, or propeptides, are cleaved from type I procollagen during collagen formation. Collagen propeptides are a marker of bone formation. Several immunoassays have been developed to measure the N-terminal (PINP)[337] and C-terminal (PICP)[377,380,527] propeptides.

Because type I collagen is also the major matrix of several other tissues, collagen propeptides are not as sensitive or specific for bone formation as osteocalcin or BAP. Measurement of procollagen peptides may be helpful for assessing bone formation in patients treated with 1,25-dihydroxyvitamin D or in patients with abnormal concentrations of this hormone when osteocalcin and BAP may be misleading.

CHAPTER 50

Pituitary Function*

Laurence M. Demers, Ph.D., F.A.C.B., D.A.B.C.C., and Mary Lee Vance, M.D.

The pituitary gland (*hypophysis*) regulates the endocrine system by integrating chemical signals from the brain with feedback from the concentration of hormones in the circulation to stimulate intermittent hormone release from target endocrine glands.[124] Historically, because it is intimately involved in the regulation of growth, development, thyroid function, adrenal function, gonadal function, and water and salt homeostasis, the pituitary has been called the "master endocrine organ."[106,124,127] It consists of two lobes of differing embryonic origin, the *anterior lobe* or *adenohypophysis* and the *posterior lobe* or *neurohypophysis*.

The adenohypophysis secretes growth hormone (GH), prolactin (PRL), thyrotropin (TSH), adrenocorticotropin (ACTH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH), all of which are proteins or peptides (see Table 28-1 in Chapter 28). It also secretes β-lipotropin (β-LPH) and a number of smaller peptides of undetermined significance.[45] Vasopressin (also known as antidiuretic hormone [ADH]) and oxytocin are produced in the hypothalamus and are carried through the neurohypophyseal nerve axons to the neurohypophysis. Thus the neurohypophysis is not a discrete endocrine organ, but rather functions as a reservoir for these two hormones.

Of the six major hormones from the adenohypophysis, GH and PRL act primarily on diffuse target tissue, with TSH ACTH, and the gonadotropins (LH and FSH) acting primarily on specific target endocrine glands (i.e., the thyroid gland, adrenal cortex, and gonads, respectively). These peptide hormones originating from the pituitary and related hormones elaborated by the placenta during pregnancy can be classified based on their molecular structure and biochemical evolution.

*The authors gratefully acknowledge the contributions of Ronald J. Whitley, A. Wayne Meikle, and Nelson B. Watts, on which portions of this chapter are based.

ANATOMY

The pituitary gland (hypophysis) is located at the base of the skull (Figure 50-1) in a bone cavity called the *sella turcica* (Turkish saddle). The gland is small—1 cm or less in height and width and weighs approximately 500 mg. As discussed previously, the gland is anatomically divided into the anterior (adenohypophysis) and the posterior (neurohypophysis) lobes. A third lobe (the intermediate lobe) is present in most vertebrates and in the human fetus; this lobe is rudimentary in the adult human.

Arterial blood reaches the pituitary gland via the superior hypophyseal artery, a branch of the internal carotid artery. Venous blood is supplied through a venous portal system that originates in the median eminence of the hypothalamus and ends in sinusoidal capillaries of the pituitary gland. This venous system is known as the *hypothalamic-hypophyseal portal system*. This system carries neurosecretory hormones from the hypothalamus to the adenohypophysis. These hypothalamic factors stimulate or inhibit the release of hormones from the adenohypophysis. Retrograde flow from the adenohypophysis to the median eminence of the hypothalamus is also believed to occur. With upstream flow, pituitary hormones can reach the hypothalamus and influence hypothalamic function through a *short feedback loop*.

Historically, cells of the human anterior pituitary lobe have been categorized into three specific types based on their staining reaction in histological sections: (1) acidophils (approximately 40% of the cells) that stain with acidic dyes; (2) basophils (about 10% of the cells) that stain with basic dyes; and (3) chromophobes (the remaining 50% of the cells) that do not stain with either acidic or basic dyes. Using modern techniques of immunohistochemistry and electron microscopy, five types of cells have been identified: (1) somatotropes that secrete GH; (2) mammotropes that secrete PRL; (3) thyrotrophs that secrete TSH; (4) gonadotropes, single cells that secrete both gonadotropins,

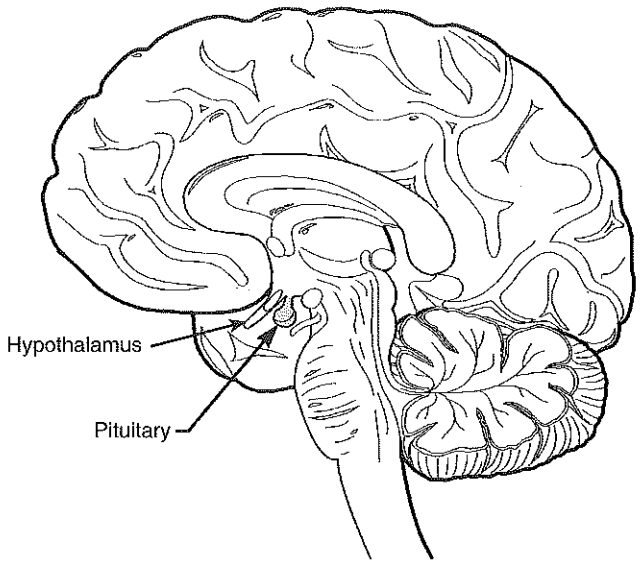

Figure 50-1 Location of pituitary and hypothalamus in the brain.

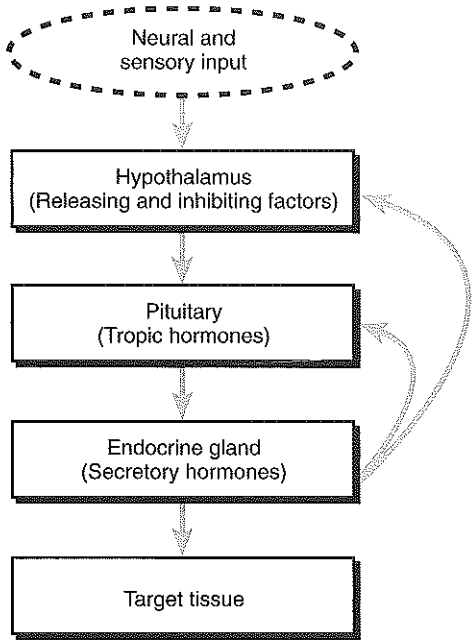

Figure 50-2 Functional interrelationship of the hypothalamus, pituitary, and endocrine glands.

LH and FSH; and (5) corticotropes that secrete both ACTH and β-LPH.

ADENOHYPOPHYSIS

The adenohypophysis and the individual hormones produced by it are discussed in this section, which concludes with a discussion of the assessment of the anterior pituitary lobe reserve.

Regulation of Function

Secretion of hormones from the anterior lobe of the pituitary gland is controlled by the hypothalamus, which manufactures small peptides known as *releasing* or *inhibitory factors* (Figure 50-2). These substances qualify as hormones because they are transported in the blood stream and produce a specific effect on the activities of a distal target tissue; however, they were initially called *releasing* or *inhibitory factors,* and these terms are still in use today. Several different hypothalamic hormones have been characterized including: (1) corticotropin-releasing hormone (CRH),[65] (2) thyrotropin-releasing hormone (TRH), (3) GH-releasing hormone (GH-RH), (4) somatostatin (also called somatotropin release-inhibiting factor [SRIF]), (5) gonadotropin-releasing hormone (Gn-RH, also called *luteinizing hormone-releasing hormone*), and (6) PRL-inhibiting factor (PIF) that is actually the neurotransmitter dopamine. In addition, Gn-RH stimulates the secretion of FSH and LH. However, a separate and distinct releasing factor for FSH has not yet been established, although negative feedback control of this gonadotropin is affected by inhibin, a peptide of gonadal origin. The principal hypothalamic hormones and their chemical nature and action are summarized in Table 50-1.

TABLE 50-1 Neurotransmitter Effect on Hormonal Secretions by the Anterior Lobe of the Pituitary Gland

	Secretion Stimulated by	Secretion Inhibited by
ACTH	Serotonin	GABA
	Acetylcholine	
	Endorphins	
TSH	Norepinephrine	Dopamine
		Serotonin
		Endorphins
PRL	Norepinephrine	Dopamine
	Endorphins	
GH	Dopamine	
	Norepinephrine	
	Serotonin	
	Endorphins	
Gonadotropins	Norepinephrine	Serotonin
	Acetylcholine	Dopamine
	GABA	Endorphins

The hypothalamic peptides, in contrast to some pituitary tropic hormones such as the gonadotropins, are not entirely species specific. Porcine Gn-RH and TRH have been shown to have an effect in humans. The availability of highly purified and synthetic releasing hormones has important diagnostic and therapeutic implications. CRH, GH-RH, Gn-RH, and TRH have all been used to test for pituitary hormone

reserve. In addition, pulsatile Gn-RH administration is used to initiate puberty and to induce ovulation or spermatogenesis. Alternately, Gn-RH antagonists that inhibit the action of endogenous Gn-RH are used to treat patients with precocious puberty, endometriosis, uterine fibroids, and prostate carcinoma. GH-RH is yet another hypothalamic peptide that is used to treat patients with GH deficiency caused by hypothalamic disease.

The neurons that elaborate hypophysiotropic hormones are themselves influenced by hypothalamic neurotransmitters, such as dopamine, norepinephrine, serotonin, acetylcholine, and endorphins. These neurotransmitters also modify the secretory activity of anterior pituitary hormones (see Table 50-1). Indeed basal and episodic secretion, diurnal rhythm, and nocturnal release of pituitary hormones are all considered to be secondary to central nervous system events that are mediated through hypothalamic hormones.

In addition to higher center regulation of the hypothalamic-pituitary axis by classic neurotransmitters, such as dopamine, there is an advancing body of evidence showing that chemical mediators released by inflammatory cells (cytokines)[4] participate in altering the control mechanisms associated with the neuroendocrine axis (see Chapter 22).[48,56,77] Modulation of the feedback loop between the hypothalamic-pituitary-adrenal axis by cytokines, such as interleukin 1 (IL-1) and IL-6, released as a result of infection or stress has been shown to diminish the immune system.[26] The concept of a hypothalamic-pituitary-adrenal-immune axis has been evolving for some time, and now substantial evidence is available to support the concept that cytokines do modulate the responsiveness of the hypothalamic-pituitary-adrenal axis under certain physiological response situations, such as infection or stress.[108]

The functional relationship that exists between the pituitary gland and its target organs is based on the principle of feedback control, which is primarily negative between the blood concentration of circulating hormones and the pituitary gland and hypothalamus (Figure 50-3). The effect of negative feedback is typically opposite to that of the initial stimulus. For example, an elevated concentration of cortisol (initial stimulus) diminishes the synthesis and release of CRH, resulting in decreased secretion of ACTH and, ultimately, reduced secretion of cortisol (final response). Conversely a diminished concentration of cortisol in the blood triggers release of CRH from the hypothalamus; this causes enhanced synthesis and release of ACTH. Increased blood concentrations of ACTH in turn stimulate the adrenal cortex to produce more cortisol. The importance of such feedback control lies in the maintenance of an optimal concentration of hormones in the blood under a fluctuating variety of circumstances. Although hormones such as thyroxine, cortisol, estradiol, progesterone, and testosterone interact with hypothalamic receptors to control the release of hypothalamic hormones, studies indicate that these secretory products directly modulate the response of pituitary cells to their respective releasing hormones. For example, pro-

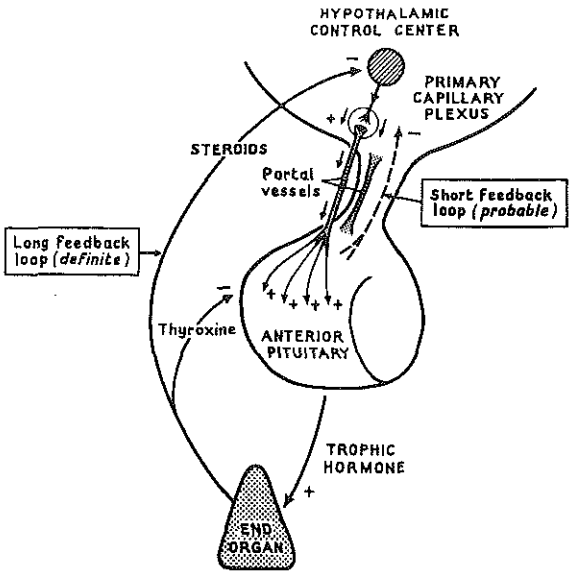

Figure 50-3 Control of anterior pituitary function. *(Modified from Catt KJ. Pituitary function. Lancet 1970;1:827-31.)*

gesterone and testosterone suppress the response of gonadotropin-producing cells to Gn-RH, whereas small doses of estradiol potentiate this response. In addition to the "long" feedback loops comprising pituitary, hypothalamic, and target gland hormones, a "short" feedback loop exists by which pituitary hormones can directly act on the hypothalamus to modify their own secretion (see Figure 50-3).

Growth Hormone and Insulin-like Growth Factors

The most abundant hormone produced by the adenohypophysis is GH. Insulin-like growth factors (IGFs) I and II are polypeptides with considerable sequence and functional similarity to insulin.

Biochemistry

GH is a single-chain polypeptide with a molecular mass of 21,500 Da that contains 191 amino acids and two intramolecular disulfide bridges. It is structurally similar to PRL and to the placental hormone chorionic somatomammotropin (hCS, placental lactogen), with which it has overlapping biological effects. Many consider GH, PRL, and hCS to have descended from a common single primordial peptide.

GH is synthesized by the somatotropic (acidophilic) cells of the adenohypophysis and is stored within intracellular granules. During the daytime hours, the plasma concentration of GH in normal adults remains stable and relatively low (<2 ng/mL), with several secretory "spikes" occurring approximately 3 hours after meals and after exercise. In contrast, during the evening hours, adults and children show a marked rise in GH secretory activity ~90 minutes after the onset of sleep; GH concentrations reach a peak value during the period of deepest sleep. This pattern of GH secretion

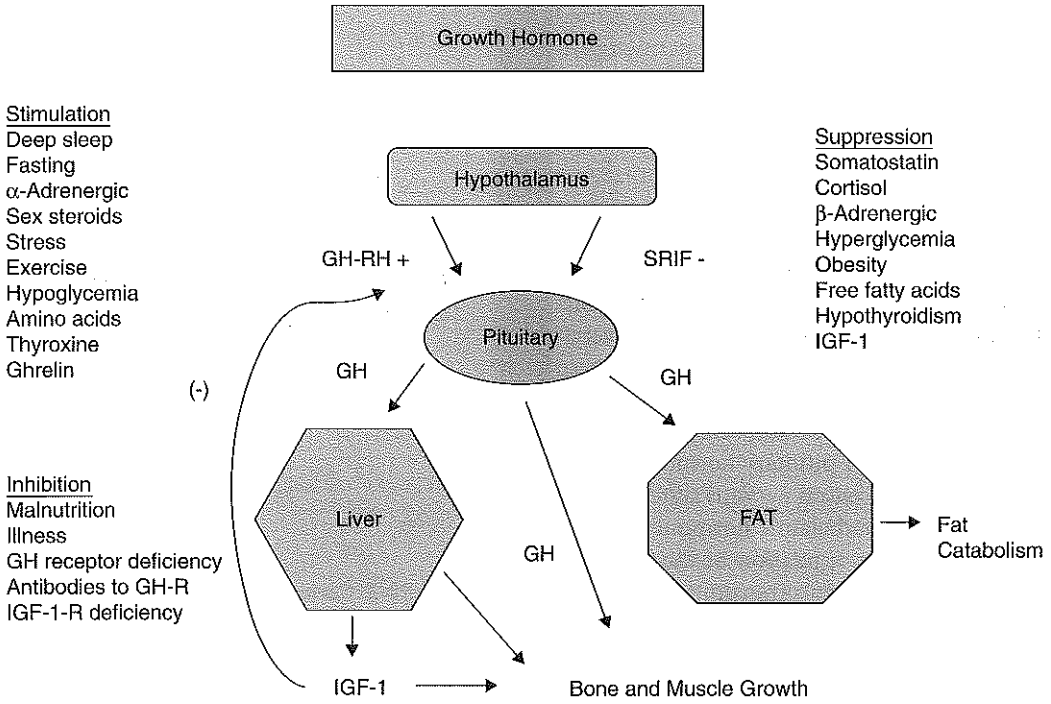

Figure 50-4 The regulatory feedback loop of the hypothalamic-pituitary-growth hormone axis. Growth hormone-releasing hormone (GH-RH) acts on the pituitary to produce GH. GH acts on the liver to produce IGF-1, which together with GH modulates bone and muscle growth and differentiation. GH also has a catabolic effect on fat tissue. IGF-1 has a negative feedback effect on GH-RH and GH secretion, and SRIF attenuates the effects of GH-RH on the pituitary.

may be important to anabolic and repair processes and for proper skeletal growth.

Regulation of Growth Hormone Secretion

The release of GH appears to be controlled by two hypothalamic factors secreted into the portal system circulation from nerve terminals in the median eminence. One of these factors is GH-RH, which stimulates GH release; the other is SRIF (somatotropin release-inhibitory factor), which inhibits GH release. (SRIF is also found in the delta cells of the pancreatic islets and in many other sites in the digestive tract; it has important effects on gastrointestinal hormone secretion and causes inhibition of insulin and glucagon release.) The hypothalamic influence on GH release appears to be predominantly inhibitory through the action of SRIF (Figure 50-4). The evidence for this comes from a twist of nature where damage to the hypothalamic-pituitary connection (e.g., resulting from pituitary stalk section and lesions of the median eminence) is followed by a dramatic decrease in both basal and provoked GH release. Release of these two hypothalamic factors is in turn influenced by higher centers of the brain. Thus different stimuli, such as exercise, physical and emotional stress, hypoglycemia, increased circulating amino acid concentrations (particularly arginine), and hormones such as testosterone, estrogens, and thyroxine, can evoke an increase in GH secretion (see Figure 50-4). In the presence of abnormally high concentrations of glucocorticoids, GH secretion is suppressed. In addition, the concentration of GH in the circulation is thought to influence the release of hypothalamic hormones through the short feedback loop. Other hypothalamic hormones, such as TRH and Gn-RH, do not affect GH release in normal subjects but may provoke GH release in patients with acromegaly.

Isolation and discovery of ghrelin support another control system for GH release in addition to GH-RH and SRIF. Ghrelin is a small 28 amino acid (AA) peptide released from neuroendocrine cells in the gastric mucosa that binds to the GH secretagogue receptor to induce the secretion of both GH-RH and GH itself. Ghrelin also induces food intake and the development of obesity.

Physiological Actions

Growth Hormone

The overall effect of GH is to promote growth in soft tissue, cartilage, and bone. This action results from stimulation of protein synthesis that is partly induced by an increase in amino acid transport through cell membranes. The effects of GH on bone and muscle are exerted both directly and through the effects of IGFs that are produced primarily in the liver and other tissue (e.g., bone) under the influence of GH. The increased growth of soft tissue and the skeleton is accompanied by changes in electrolyte metabolism, including a positive nitrogen and phosphorus balance, a rise

in plasma phosphorus concentrations, and a fall in blood urea nitrogen and amino acid concentrations. Additional responses to GH include increased intestinal absorption of calcium and decreased urinary excretion of sodium and potassium. The metabolic changes are most likely a result of the increased uptake of these ions by growing tissue. GH has other effects on intermediary metabolism. GH stimulates the uptake of nonesterified fatty acids by muscle and accelerates the mobilization and metabolism of fat from adipose tissue to the liver. Acutely, GH causes a decrease in blood glucose concentrations; however, chronic GH excess stimulates hepatic glycogenolysis and antagonizes the effect of insulin on glucose uptake by peripheral cells (see Metabolism of Carbohydrates, Chapter 25) leading to an increase in blood glucose concentrations. GH and insulin induce growth in a similar manner, because both have protein anabolic effects and stimulate the transport of amino acids into peripheral cells. Their respective effects on glucose homeostasis, however, oppose each other. Most growth-promoting GH effects are delayed rather than immediate and are exerted primarily through IGF-I.

Insulin-Like Growth Factors[110]

The first GH-dependent growth factor to be isolated was termed *sulfation factor*, because of its ability to enhance the incorporation of sulfate into cartilage. However, this substance had other effects on cartilage, including the stimulation of deoxyribonucleic acid (DNA) and ribonucleic acid synthesis and collagen formation. Initially, this factor and other peptides with similar biological activities that are stimulated by GH were called *somatomedins*. Later this term was changed to *insulin-like growth factor* because of the peptides' structural similarities to insulin.

The most important of the IGFs is IGF-I. In addition to its growth-promoting effects on cartilage, IGF-I also shows insulin-like activity in other tissue. IGF-I increases glucose oxidation in adipose tissue and stimulates glucose and amino acid transport into diaphragmatic muscle and heart muscle. Synthesis of collagen and proteoglycans is enhanced by IGF-I, which also has positive effects on calcium, magnesium, and potassium homeostasis. The insulin-like effects of this growth factor have been ascribed in part to its structural similarity to insulin. Unlike most other peptide hormones, IGFs circulate in blood complexed to specific plasma-binding proteins. Six major IGF-binding proteins have been identified in human plasma.[110] Insulin-like growth factor binding protein (IGFBP)-3, a glycosylated binding protein, complexes >75% of the circulating IGF-I. The concentration of this binding protein is GH dependent and provides for a circulating reserve pool of IGF-I. Dissociation of the IGFs from the binding proteins occurs before passage through capillary membranes and entrance into dense tissue, such as cartilage.

Plasma concentrations of immunoreactive IGF-I rise during childhood and achieve adult concentrations by the time of puberty. During puberty, IGF-I concentrations can be two to three times the adult concentration. During adolescence, IGF-I concentrations show a gradual decline, reaching a steady state in the third decade of life. IGF-I concentrations are increased as expected in patients with acromegaly[85] and are reduced in GH deficiency states and in many other forms of growth retardation, hypothyroidism, chronic illness, nutritional deficiency, and liver disease.

Clinical Significance

Clinically important states of GH excess or deficiency are relatively uncommon and often difficult to diagnose.[101,131] GH concentrations vary widely under normal circumstances, so the measurement of GH under random conditions is not generally considered useful. A single GH measurement cannot be used to distinguish normal fluctuations from the low or high concentrations that are seen in various disease states. GH measurements are best determined as part of dynamic testing that involves the use of pharmacological or physiological provocative stimuli to stimulate or suppress GH release.[37]

In contrast to GH, a single measurement of IGF-I is considered an accurate reflection of IGF-I production.[100] Serum concentrations of IGF-I are influenced by age, degree of sexual maturation, and nutritional status. As mentioned previously, IGF-I concentrations are low in states of GH deficiency but also in patients with acute or chronic protein or caloric deprivation.

Growth Hormone Excess

Excess GH production is associated with eosinophilic or chromophobe adenomas[21] of the pituitary gland; these tumors are sufficiently large to be demonstrated using computed tomography or magnetic resonance imaging in approximately 75% of patients. Prolonged exposure to GH excess causes an overgrowth of the skeleton and soft tissue. This occurs most commonly in adults and is known as *acromegaly*.[31,135] When GH excess is seen before long-bone growth is complete, the condition is called *pituitary gigantism*. With pituitary gigantism, in addition to the overgrowth of bone and soft tissue particularly evident in the face and extremities, there is a striking acceleration of linear growth. In severe or advanced cases of GH excess, the diagnosis can be made on the basis of physical appearance alone; however, the physical changes are often subtle and gradual, so that a high degree of clinical suspicion is needed to make an early diagnosis. The reversibility of the tissue changes depends largely on the duration of the disease. In addition to the soft-tissue changes, acromegaly may cause severe disability or death from cardiac or neurological sequelae. The most important requirement for the diagnosis of acromegaly is the demonstration of inappropriate and excessive GH secretion.[88]

GH-secreting pituitary tumors account for most of the cases of acromegaly. Patients who have pituitary tumors that produce GH are frequently shown to release GH in response to other hypothalamic peptides (TRH and Gn-RH) that

under normal circumstances do not elicit a release of GH. On occasion, pituitary tumors that produce excess amounts of both GH and PRL are observed. Few cases of acromegaly, however, are due to GH-RH hypersecretion by tumors.

As many as 10% of patients with active acromegaly have random serum GH concentrations that fall within the normal reference interval.[88] Essentially, all patients with acromegaly have an abnormal response to oral glucose (see Box 50-1). Patients with acromegaly typically show either no change in their basal concentration of GH or demonstrate a paradoxical increase in GH[36]; normal individuals, on the other hand, show suppression of GH concentrations to <1 ng/mL after the oral ingestion of glucose.

BOX 50-1 Protocol for Glucose Suppression of Growth Hormone Test

Rationale Normal subjects show suppression of serum GH concentrations after oral administration of glucose; subjects with acromegaly fail to show this suppression.

Procedure The test should be performed after an overnight fast with the patient maintained at bed rest. After a baseline blood specimen is collected for GH measurement, a solution of 75 g of glucose is given orally; serum GH is measured again on specimens collected 60 and 120 minutes later.

Interpretation Serum GH concentrations in normal individuals fall to <2 ng/mL; subjects with acromegaly fail to show this suppression and sometimes show a paradoxical increase in GH concentration. Patients with liver disease, uremia, or heroin addiction may have false-positive results with this test (failure to suppress serum GH concentrations after oral glucose load).

GH, Growth hormone.

Serum IGF-I concentrations are elevated in active acromegaly (Figure 50-5). IGF-I concentrations often correlate better with the clinical severity of acromegaly than with glucose-suppressed or basal GH concentrations.[27]

Growth Hormone Deficiency States and Growth Retardation

Children who have inadequate GH production or a GH receptor defect do not grow normally. GH deficiency may be (1) congenital or acquired; (2) idiopathic or caused by anatomical damage to the pituitary gland or hypothalamus; or (3) caused by isolated or associated deficiencies of other pituitary hormones. In one reversible GH deficiency state known as *psychosocial dwarfism,* environmental stress has been shown to inhibit pituitary and hypothalamic function, leading to GH suppression and growth retardation. Children with this disorder show clinical and chemical evidence of growth deficiency when first evaluated but usually have normal pituitary function after a few days of hospital stay. GH deficiency is not a common cause of growth retardation; about one half of the children evaluated for growth retardation have no specific organic cause. About 15% of children with growth retardation have endocrine problems, and approximately one half of these (about 8% of all children with short stature) have GH deficiency. However, children with growth retardation or dwarfism with no clear explanation should at least be screened for GH deficiency. With the availability of recombinant GH for therapeutic use, many children with short stature are now being selectively treated with GH to advance their growth pattern to closer toward normal.

GH deficiency in adults is probably the most common demonstrable abnormality in patients with large pituitary

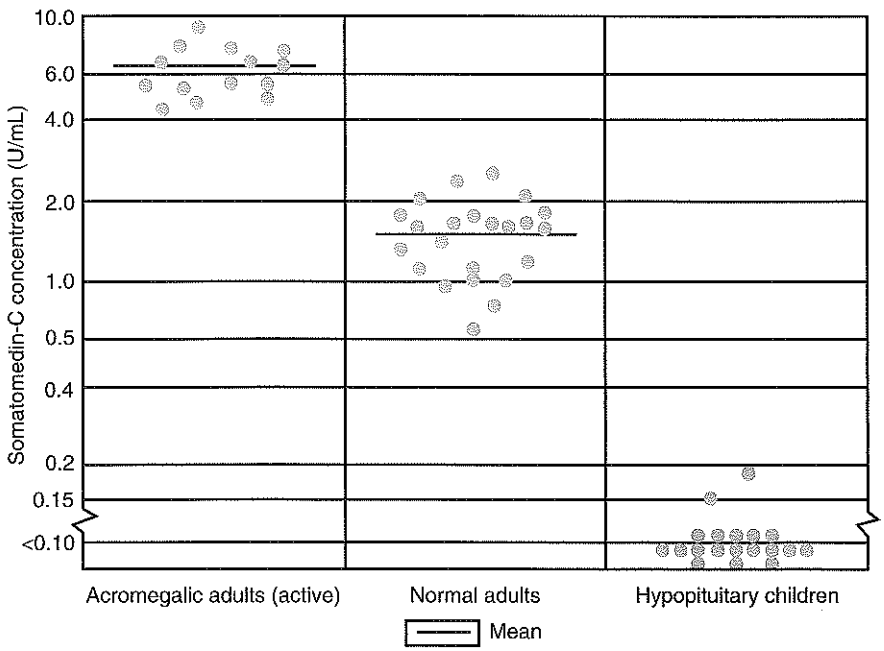

Figure 50-5 IGF-I concentrations in growth hormone excess and deficiency states. *(Reproduced with permission Van Wyk JJ, Underwood LE. Growth hormone, somatomedins, and growth failure. Hosp Pract 1978;13:57-67. Illustration by Albert Miller.)*

adenomas[21] or patients who have undergone pituitary irradiation; GH deficiency in adults can lead to premature mortality, abnormal body composition, impaired serum lipids, decreased bone density with an increase in fracture risk, and overall, an impaired quality of life. Thus GH replacement therapy is an important clinical intervention in GH-deficient adults and considered the standard of care.

Insensitivity to GH results in growth failure despite normal or increased serum GH concentrations. Patients who have familial short stature and high serum GH or low serum IGF-I concentrations[72] probably represent many different defects in genetic coding for the GH receptor that result in the absence of or defective GH receptors. In affected individuals, exogenous GH fails to produce any appreciable metabolic changes or to promote growth. In normal individuals, the basal concentration of GH is usually low, and the half-life of circulating GH is rather brief (~20 minutes). Moreover, GH is secreted by the pituitary gland in short pulses or bursts. Thus assays of GH performed on a single random or fasting specimen may not distinguish patients with abnormally low concentrations from healthy subjects who have GH values at the low end of normal. When evaluating GH reserve, provocative tests are frequently used to sort out a true deficiency. Although a normal GH response to a provocative test is a strong indication for the absence of GH deficiency, no single test can be considered diagnostic in this situation; as many as 30% of subjects with normal GH secretion fail to show the expected elevation in serum GH in response to a specific provocative stimulus at any given time. For this reason, to diagnose GH deficiency as a cause of growth retardation, it is necessary to demonstrate that the serum concentration of GH remains low after the use of at least two different provocative stimuli.[37,78] The definition of subnormal responses, however, is arbitrarily defined and assay dependent. In general a GH response >7 to 10 ng/mL after stimulation is considered normal.

A number of physiological and pharmacological circumstances provoke GH release. Some of these are presented in Table 50-2 and Figure 50-4. In one simple screening test, the patient performs 20 minutes of vigorous exercise, and then a sample is obtained for a GH measurement (Box 50-2).[62] Taking advantage of the known rise in the concentration of GH that occurs with deep sleep, a sample may be obtained 60 to 90 minutes after the onset of sleep.[80] The obvious limitation of this approach is that the patient must be in the hospital or a clinical research center for testing. The infusion of insulin[103] (Box 50-3) and arginine[86,96] (Box 50-4) are the standard pharmacological stimuli used to test for GH release; protocols for their use are well established and standardized. Other medications used to stimulate GH release

TABLE 50-2 Stimuli for Growth Hormone Release

Test	Test Conditions and Dosages	Time of Peak Growth Hormone Release	References
Exercise	20 min of vigorous exercise	20 min after exercise has begun	62
Sleep	Sample drawn 1 hr after the onset of deep sleep (stage III or IV); EEG documentation if possible	Usually 1 hr after onset of deep sleep, coincident with onset of stage III or IV sleep	80
Arginine*†	Arginine hydrochloride, 0.5 g/kg body weight, given intravenously over a 30-min period	60-120 min	87, 96
Insulin*†‡	Regular insulin, 0.1-0.15 U/kg, IV push (severe hypoglycemia may result, and a physician should be in constant attendance)	45-75 min	103
Glucagon†	0.03 mg/kg IM or subcutaneously (not to exceed 1 mg)	120-180 min	114
L-Dopa	0.5 g/1.73 m^2, usually given with lunch (responses may be improved by giving priming doses of L-dopa, 0.25 g/1.73 m^2, for 1 or more days before the test)	30-120 min	38
Clonidine	0.15 mg/m^2	90 min	46
Diazepam	0.15 mg/kg, orally	60 min	70
Pentagastrin	IV infusion, 1.5 mg/kg/hr	75 min	38

EEG, Electroencephalography; *IV*, intravenous; *IM*, intramuscular.

*Sequential administration of arginine and insulin may reduce the need for additional testing.[98]

†Propranolol, 0.75 mg/kg (20 to 40 mg orally), given 30 to 60 minutes before glucagon, insulin, or arginine may enhance a normal response.[97]

‡Insulin, TRH, and Gn-RH can be given as a "cocktail" to evaluate GH, ACTH, TSH, PRL, LH, and FSH in a single test period.[113]

BOX 50-2 Protocol for the Exercise Stimulation Test for Growth Hormone

Rationale Brisk exercise normally causes an increase in serum GH concentrations.

Procedure The test is best performed in the morning after an overnight fast, but may be done at any time. Vigorous physical exercise (running or calisthenics) is performed for 20 minutes. A venous blood specimen for determination of GH is drawn immediately after termination of exercise.

Interpretation If the serum GH concentration is >7 ng/mL, GH deficiency is unlikely. An intermediate response (3 to 6 ng/mL) should be considered suspect and further testing performed if clinically warranted. A subnormal response is not diagnostic for GH deficiency and should be confirmed with a second provocative test.

GH, Growth hormone.

BOX 50-3 Protocol for the Insulin-Induced Hypoglycemia Stimulation Test (Insulin Tolerance Test)

Rationale The stress of insulin-induced hypoglycemia triggers the release of GH and ACTH from the pituitary gland in normal subjects. GH response is measured directly; cortisol is measured as the indication of ACTH response.

Procedure The test is done after an overnight fast with the patient at bed rest. An indwelling needle or IV line is inserted. Sampling is begun after a 30-minute rest period. Baseline samples are drawn for determination of glucose, GH, and cortisol. Regular insulin, 0.1 to 0.15 units/kg body weight, is injected intravenously. Samples are then obtained at 30, 60, and 90 minutes for glucose, GH, and cortisol determinations. To be confident that an adequate stress has been applied, the patient must become symptomatic (exhibit sweating or tremor), or the glucose concentration must fall to <40 mg/dL (2.2 mmol/L). Additional IV insulin may be given if this has not occurred by 30 minutes, in which case sampling should be prolonged by 30 minutes. The physician should be in attendance throughout the test, and 50% dextrose for IV administration should be kept on hand to be used in the event of severe hypoglycemic reaction and after adequate hypoglycemia has been documented. The test is contraindicated in patients with seizure disorders, ischemic heart disease, or cardiovascular insufficiency.

Interpretation The serum cortisol concentration should increase to a peak value of >20 µg/dL (550 nmol/L). Serum GH concentration should rise to a peak value of >10 ng/mL. No response or inadequate responses may be due to pituitary hormone deficiency or to a hypothalamic lesion.

GH, Growth hormone; *ACTH,* adrenocorticotropin.

BOX 50-4 Protocol for the Arginine Stimulation Test for Growth Hormone

Rationale In normal subjects, IV administration of arginine hydrochloride stimulates GH release.

Procedure The test should be done after an overnight fast with the patient maintained at bed rest. Arginine hydrochloride, 0.5 g/kg body weight, is infused intravenously over 30 minutes. Blood samples are drawn for determination of GH before the infusion is started and 30, 60, and 90 minutes after the infusion is begun.

Interpretation The GH concentration should rise at least threefold above the baseline value to a peak value >10 ng/mL. A subnormal response is seen in GH-deficient subjects. A subnormal GH response is not diagnostic for GH deficiency and should be confirmed with a second provocative test.

GH, Growth hormone.

include glucagon. GH-RH administration intravenously has also been used to test for pituitary GH reserve directly to distinguish between a hypothalamic or a pituitary-based defect in GH release.

As expected, IGF-I concentrations are low in patients with GH deficiency and growth failure (see Figure 50-5). Patients with growth failure caused by other endocrine diseases or by nonendocrine organic diseases can also have low circulating concentrations of IGF-I; thus a low concentration of IGF-I is not a specific indication of GH deficiency. The presence of a normal concentration of IGF-I, however, does rule out severe GH deficiency.

Measurement of Growth Hormone in Blood and Urine

Bioassays, receptor assays, and immunoassays are used to measure GH.[100A] Most bioassays assess GH activity by analyzing a variety of growth-related metabolic changes in hypophysectomized rats or in cell cultures. A relatively simple and convenient bioassay, the *Nb2 cell assay,* uses cultures of GH-sensitive rat lymphoma cells.[123] These bioassays are used primarily for calibrating GH reference materials or for comparing the biological potency and immunoreactivity of GH fragments and synthetic peptides. Receptor assays have also been applied to the measurement of GH, but their use has been limited to research applications.

Binding assays that use specific GH antibodies are preferred for routine laboratory use. For many years, serum concentrations were measured by radioimmunoassay (RIA) using reagents provided by the United States National Hormone and Pituitary Program (NHPP; http://www.humc.edu/hormones/), which was formerly known as the National Pituitary Agency. Today a variety of isotopic and nonisotopic assays are commercially available. Many use polyclonal antibodies produced in rabbits or in guinea pigs against purified pituitary preparations of the unmodified, monomeric hormone. However, an increasing number of

GH assays now use mouse monoclonal antibodies, and some of these assays are able to discriminate GH variants. Most procedures use recombinant-derived GH for labeling with a tracer and calibration material. The latter is usually prepared gravimetrically and verified by comparison with an international reference preparation (IRP), such as the World Health Organization's (WHO's) international standard, IRP 80/505 human growth hormone recombinant (hGHr), which has a potency of 3.3 IU/mg of r-hGH, or other standard preparations, such as WHO IRP 66/217 or 88/624. The assay diluent, however, can vary considerably from one assay to another and is a potential source of bias; some commercial kits use phosphate-buffered saline, and others use horse, calf, or human serum.

Sensitive immunometric assays that use excess labeled antibodies in noncompetitive formats have been developed for measuring GH.[126] Several of these two-site "sandwich" assays are commercially available. Most are immunoradiometric assays (IRMAs) that are based on the use of two monoclonal antibodies directed at different antigenic sites on the GH molecule; one of the antibodies is labeled with ^{125}I, the so-called signal antibody, and the other antibody referred to as the capture antibody is anchored to a solid phase separation system. These isotopic methods for measuring GH are, however, gradually being replaced with assays that employ monoclonal antibodies coupled to either a nonisotopic enzyme,[130] a chemiluminescence tagged antibody, or a fluorescent[122] label. The detection limit of these immunometric assays ranges from 0.1 to 0.5 µg/L.

Problems

Human GH is not a single molecular species but is present in the pituitary gland and in the circulation as a heterogenous mixture of structural isoforms.[11,111,120] Normally the human gene for GH directs the synthesis of a monomeric 22-kDa protein that accounts for 75% of the GH found in the circulation. In addition to this predominant form, however, approximately 10% of GH from human pituitaries is present in plasma as a 20-kDa protein. This smaller form lacks amino acid residues 32 to 46 and is probably a product of posttranslational processing. Fractionation of serum by gel filtration also reveals the presence of aggregates and oligomers of GH. These large molecules are often referred to as "big" and "big-big" forms. The big forms are predominantly dimers of the monomeric hormone, whereas the big-big forms are mainly complexes formed by GH and its serum-binding protein. All of these GH variants are antigenic; in normal plasma, 75% of immunoreactive GH consists of monomeric forms, 18% are present in dimeric forms, and 7% in oligomeric forms.

Analytically the presence of GH variants in serum often leads to problems with quantitation and to discrepancies among the results given by different assays.[55] The use of (1) different antibodies, (2) different calibration materials, (3) different labels, and (4) different assay diluents further increases the complexity of GH measurements. For example, immunometric assays using monoclonal antibodies tend to give lower GH estimates than polyclonal RIAs and may not recognize some forms of the hormone.[107] Discordant results have also been noted among immunometric assays. One commercial IRMA, for example, detects the 20-kDa variant of GH, whereas another IRMA does not[25]; the dimeric form of GH interferes with some immunometric kits but not with others.[19] Variations in assay performance can also be attributed to the inappropriate use of serum proteins from animal sources in buffer diluents.[41] In addition, the calibrators used in most GH assays are derived from pituitary extracts and thus may not reflect the concentrations and types of GH variants present in the specimen being assayed. However, the use of recombinant standards for GH has improved this problem and it has been suggested that the 22-kDa form of GH be used to establish uniformity of results between methods.

Variations in GH isoform detection can seriously affect the interpretation of GH stimulation tests when using different GH assays. For example, one assay may indicate an adequate amount of GH following a stimulation test, whereas another might give a low estimate of the GH concentration that could lead to misclassification of a child as GH deficient. It is important therefore that cutoff values and reference intervals be established separately for each method proposed for routine use to prevent misinterpretation and a misdiagnosis.[8] Moreover, particular care should be taken when comparing serum GH values obtained using different immunoassay systems.

Most GH assays are performed with serum specimens, but the highly sensitive immunometric assays have been modified to allow for direct measurement of GH in untreated urine.[40,47] Because the concentration of GH in urine is only 0.1% of that in serum, conventional RIAs usually require preliminary extraction and concentration procedures.

Specimen Collection and Storage

The preferred specimen is serum; plasma with ethylenediaminetetraacetic acid (EDTA) or heparin added to prevent coagulation may also be used, but values are method dependent. Serum specimens should be stored at 2 °C to 8 °C if they are not to be tested within 8 hours. If they must be stored for long periods, serum samples should be frozen at –20 °C or colder.

Reference Intervals

The following intervals are based on a competitive RIA technique that is calibrated against the WHO IRP 80/505 for r-hGH.

	µg/L
Basal	2-5
Insulin tolerance test	>10
Arginine	>7.5
L-Dopa	>7.5

Comments

A single basal or random concentration of GH provides little diagnostic information. Secretion of GH by the pituitary gland is both episodic and pulsatile, and transient concentrations of up to 40 ng/mL have been observed in normal, healthy subjects. Serum concentrations are rather low between pulses in healthy individuals, and some immunoassays may not be able to distinguish patients with abnormally low values from healthy subjects who have values that happen to fall in the low-normal reference interval. In some individuals, spontaneous GH secretion is better monitored using a continuous withdrawal pump or by drawing specimens for GH assay every 20 to 30 minutes over a 12- to 24-hour period. To interpret meaningful GH concentrations, a number of provocative tests have been established to stimulate or suppress GH release. The insulin tolerance test, which produces a transient hypoglycemia to provoke GH release, is the most common stimulation test used to assess adequacy of GH secretion.

Measurement of Insulin-Like Growth Factors

IGFs are measured in plasma or serum by a variety of methods including in vitro bioassay, radioreceptor assay, or immunoassay techniques.[71] Most bioassays measure the sum of IGF-I and IGF-II bioactivity using rabbit chondrocytes, chick pelvic cartilage, or porcine rib cartilage.[111] Such assays are relatively imprecise, insensitive, and often not specific.

The original immunoassays for IGF-I (somatomedin C) were based primarily on double-antibody methods under equilibrium or nonequilibrium conditions and on the use of ^{125}I-labeled tracers.[111] Purified preparations of IGF-I isolated from human serum generally serve as calibrators, although recombinant IGF-I is now available and used in some procedures. The IGF-I standards are calibrated against the WHO preparation IGF-I 87/518. To remove interfering IGF-binding proteins, most assays preextract serum specimens by a variety of methods, such as gel filtration, acid-ethanol precipitation, cryoprecipitation, C18 Sep-Pak column extraction, or reversed-phase chromatography.[20] Direct (no extraction) procedures are also available, but extraction methods prevent complex problems associated with the presence of carrier proteins and serum proteases. Moreover, extraction procedures better discriminate GH-deficient patients from age-matched controls. Commercial RIA, IRMA, and assays that employ chemiluminescence signaling are available for measuring IGF-I, usually with minimal cross-reactivity to IGF-II (0% to 3%).[64,118] A typical IRMA procedure calls for incubating extracted serum specimens with two different monoclonal antibodies either for 3 hours at room temperature or overnight (16 to 18 hours) at 2 °C to 8 °C. The signal antibody is labeled with ^{125}I, and the capture antibody is attached to the inner walls of plastic test tubes or free in solution. Interassay coefficients of variation for most methods range between 5% and 10% across a wide analytical range. It is important to establish age-related reference interval for IGF-I because of the marked differences in concentrations that exist between adults and children.

Immunoassays for IGF-II complement the measurement of IGF-I. Together they provide better identification of GH-deficient children. The IGF-II assay, like that for IGF-I, is best performed after the removal of high molecular weight binding proteins. Adding excess IGF-I to each tube[16] can block interference from smaller IGF-binding proteins; the use of highly specific antisera ensures negligible cross-reactivity with related molecules, such as IGF-I and insulin. Single measurements of IGF-binding protein 3 (IGFBP-3), the major protein carrier of IGFs in circulation, can also provide additional information for the determination of GH deficiency. This protein can be quantitated in unextracted plasma by RIA using rabbit antihuman IGFBP-3; cross-reactivity with other binding proteins is <0.2%.[17]

Specimen Collection and Storage

Serum or plasma (with heparin or EDTA added to prevent coagulation) can be used depending on the assay method. Samples should be centrifuged within 1 hour of collection and stored frozen at −20 °C or colder until assay. It is recommended that storage before assay under these conditions not exceed 30 days. Some procedures use dried whole blood or serum collected on filter paper.[89]

Reference Intervals

Published intervals for IGF-I differ because of variations in methods and calibration. The values listed on p. 1977 are expressed in nanograms per milliliter of synthetic peptide; dividing by 220 converts IGF-I values to units per milliliter, where one unit is arbitrarily defined as the amount of IGF-I in a pool of normal adult human sera.[39]

IGF-I concentrations are highly age dependent. For the care of adolescent patients, reference values are based on Tanner stage and chronological age. (Tanner staging is a classification of pubertal development based on the manifestation of secondary sex characteristics; many hormones involved in adolescent growth are more closely related to Tanner stages than to chronological age.[134]) By comparison, IGF-II concentrations are relatively unaffected by differences in maturity. A typical adult reference interval for IGFBP-3 is 0.9 to 4.0 mg/L.[90]

Prolactin

Prolactin (PRL) is a hormone secreted by special cells of the adenohypophysis. It stimulates and sustains lactation in postpartum mammals, the mammary glands having been prepared by other hormones, including estrogens, progesterone, growth hormone, corticosteroids, and insulin. It also stimulates formation of "milk" in the crop sac of birds, such as pigeons and doves (an action formerly used for bioassay), is luteotropic in certain mammals, and has many other

IGF-I (ng/mL)[125]

By Chronological Age			By Tanner Stage		
Age (yr)	Males (ng/mL)	Females (ng/mL)	Stage	Males (ng/mL)	Females (ng/mL)
1-2	31-160	11-206	1	215 ± 71	225 ± 83
3-6	16-288	70-316	2	320 ± 137	410 ± 84
7-10	136-385	123-396	3	475 ± 176	492 ± 180

effects, including essential roles in the maintenance of immune system functions. It is called also *lactogen, lactotropin, luteotropin, mammotropin,* and *galactopoietic, lactation, lactogenic,* or *luteotropic hormone.*

Biochemistry

The structure of PRL is similar to that of GH in that the human gene for PRL located on chromosome 6 arose from a single common ancestral gene, which gave rise to not only PRL but to GH and placental lactogen-related peptides. PRL contains 199 amino acids and has three intramolecular disulfide bridges. Its molecular mass is 22,000 Da. It is secreted by the pituitary lactotroph cells, which are acidophilic. PRL circulates in the blood in different forms; monomeric PRL, 23 kDa (referred to as little PRL), dimeric PRL, 48 to 56 kDa (so-called big PRL), and polymeric forms of PRL >100 kDa (called "big-big" PRL). The monomeric form is considered the most bioactive of the different forms found in the circulation and demonstrates the greatest response to TRH, the hypothalamic releasing factor that stimulates the pituitary to release PRL. The relative number and PRL content of lactotroph cells are increased in women during pregnancy and also found elevated in fetal pituitary glands. The increase in the number of lactotroph cells during pregnancy is the result of the elevated concentration of circulating estrogens present in pregnancy.

Secretion of PRL, as for other hormones released by the anterior lobe of the pituitary gland, falls under hypothalamic control. PRL is unique, however, among the adenohypophyseal hormones in that the primary control of its secretion is inhibitory rather than stimulatory (Figure 50-6). Dopamine is believed to be the principal PIF that tonically regulates PRL secretion by binding to the D2 receptors on pituitary lactotrophs. Other factors, such as endothelin-1 and transforming growth factor β1, can also inhibit PRL release. In contrast, TRH is a potent PRL releasing factor (PRF) and stimulates PRL secretion within minutes when injected intravenously into human subjects. TRH, however, is not the only PRF, because hypothalamic extracts cause PRL release even when the TRH content has been inactivated or removed. Factors such as vasoactive intestinal peptide, epidermal growth factor, and estrogen also stimulate PRL release. The regulation of PRL is not altered in experiments with anti-TRH antibody, and suckling, which causes a sharp rise in plasma PRL, does not affect TSH secretion. Thus these other PRFs play an important role in PRL secretion. As with other adenohypophyseal hormones, the release of PRL is episodic and varies predictably during the day, with lowest concentrations found at midday and highest values shortly after the onset of deep sleep. The major physiological stimulus for PRL release is suckling, and maternal plasma PRL concentrations increase within minutes after the initiation of breast-feeding. Following labor and delivery, PRL concentrations remain elevated longer when the newborn is breast-fed. Other stimuli induce PRL release, probably through suppression of dopamine releasing the pituitary from its inhibitory effects; stress is one of these stimuli. ACTH concentrations, which are also increased with stress, can cause an elevation in plasma PRL values. Plasma hyperosmolality is yet another stimulus for PRL release, whereas hypoosmolar conditions induce a decrease in plasma PRL concentrations. Whether this effect is stress related or is associated with the role of PRL in the control of osmolality has not been established. Finally an important influence on PRL regulation appears to be exerted by PRL itself by way of a short feedback loop between the pituitary and hypothalamus. PRL participates in negative feedback to control its own release by increasing the concentration of tyrosine hydroxylase activity in the neurons that produce dopamine. Short-

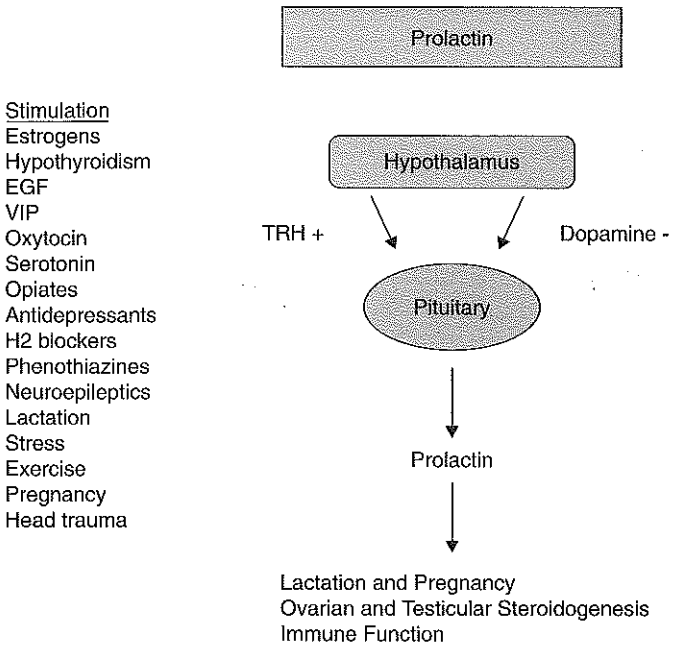

Figure 50-6 Regulatory control of PRL release. TRF along with a variety of other factors stimulates the release of PRL from the pituitary. Dopamine and other factors are inhibitory to PRL release.

feedback-loop inhibition of Gn-RH secretion by PRL has also been suggested as the reason for the inhibition of gonadotropin secretion that occurs in women who are nursing and in patients with PRL-secreting adenomas of the pituitary gland.

Physiological Action

The principal hormone that controls the initiation and maintenance of lactation is PRL. However, for an appropriate expression of PRL action, breast tissue requires priming by estrogens, progestins, corticosteroids, thyroid hormone, and insulin. PRL induces ductal growth, development of the breast lobular alveolar system, and the synthesis of specific milk proteins, including casein and γ-lactalbumin. PRL has effects on the immune system[138] and is important in the control of osmolality and various metabolic events, including the metabolism of subcutaneous fat, carbohydrate metabolism, calcium and vitamin D metabolism, fetal lung development, and steroidogenesis. This last function may be related to its antigonadotropic effect.

PRL, like other pituitary hormones, binds to a specific receptor on the cell membrane of its target organs (breast, adrenal, ovaries, testes, prostate, kidney, and liver). However, the exact intracellular mechanism of PRL action is not known. It has been suggested that PRL regulates the transport of lipoproteins in the adrenal gland, ovary, and testis to ensure a constant supply of low-density lipoprotein cholesterol for steroidogenesis. In addition, PRL promotes the synthesis of enzymes of the adrenal androgen pathway, thus facilitating the conversion of pregnenolone to dehydroepiandrosterone and dehydroepiandrosterone sulfate (see Adrenocortical Steroids, Chapter 51). PRL can also stimulate the enzyme 3-β-ol-dehydrogenase in the gonads, resulting in increased testosterone production and ovarian steroid biosynthesis, particularly the synthesis of progesterone.

Clinical Significance

When assays for PRL became routinely available in the early 1970s, it became apparent that patients with elevations in PRL were observed more frequently than previously thought in clinical practice.[67,99] However, PRL deficiency does not appear to have clinical significance except as an additional test of pituitary function in patients already known to have pituitary disease.

Hyperprolactinemia is the most common hypothalamic-pituitary disorder encountered in clinical endocrinology.[66] PRL concentrations also may be elevated in women who have only subtle alterations of fertility, such as (1) anovulation with or without menstrual irregularity, (2) amenorrhea and galactorrhea, or (3) galactorrhea alone. PRL excess in men is frequently manifested as oligospermia or impotence or both. In addition, men with PRL-secreting pituitary adenomas more often present with macroadenomas and visual field disturbances as a result of a larger tumor pressing on the optic chiasm. Men do not have the subtle reminder of an irregular menstrual period that can frequently expose a microadenoma in women. Elevated PRL concentrations are observed in as many as 30% of patients with polycystic ovarian syndrome and patients with clinically silent pituitary adenomas. Other causes of PRL elevation are shown in Box 50-5 and Figure 50-6 and should be kept in mind when evaluating patients who present with an elevated concentration of PRL. There is no reliable

BOX 50-5 Causes of Prolactin Elevation

Chronic renal failure
Pregnancy
Breast stimulation or chest wall trauma
Primary hypothyroidism
Empty sella syndrome
Pituitary adenoma (microadenoma or macroadenoma)
  "Nonsecretory"
  With galactorrhea and amenorrhea or oligospermia
Idiopathic
Drugs
  Dopaminergic-blocking agents: phenothiazines, butyrophenones, benzamides (metoclopramide, sulpiride)
  Dopamine-depleting agents: α-methyldopa, reserpine
  Noncatecholamine-dependent agents: TRH, estrogens
  H_2-receptor blocking agents: cimetidine
  Tricyclic antidepressants
Hypothalamic etiologies

stimulation or suppression test as with other pituitary hormones to distinguish tumor from nontumor causes of PRL elevation.

Basal gonadotropin concentrations are low in most patients with hyperprolactinemia; most studies suggest that PRL inhibits the release of Gn-RH, resulting in a state of functional hypogonadotropism. Other pituitary function tests are usually normal in patients with hyperprolactinemia, except in individuals with very large tumors. It has been reported that the usual nocturnal increase in PRL is blunted in patients with pituitary adenomas and hyperprolactinemia but not in normal subjects or patients with the empty sella syndrome. A ratio of greater than 1:2 in night-to-day PRL is considered normal. The extent of PRL elevations in patients with PRL-secreting pituitary adenomas is generally greater than is seen with other nonadenoma causes of a PRL elevation. However, none of the laboratory approaches used to evaluate a prolactinoma is sufficiently definitive to differentiate hyperprolactinemia from nonpituitary causes from that caused by pituitary disease.

If a borderline elevation of PRL is found, it is advisable to repeat the measurement on at least two other occasions, taking care to obtain the specimen with minimal excitement or stress to the patient, no trauma, no breast stimulation, and in the morning; the patient should also not be on any medication that could stimulate PRL release.

Clinically, medications that can stimulate PRL release are the single most common cause for creating a biochemical picture of a prolactinoma in an otherwise healthy individual. When a significant elevation of PRL is confirmed, a careful history must be recorded to rule out the possibility that medications are not the cause for the elevation in PRL. A significant list of medications has been identified that have spuriously elevated PRL concentrations in an otherwise normal individual. In addition to estrogens, dopamine receptor blockers, such as the phenothiazines, and dopamine antagonists, such as metoclopramide and domperidone used to treat gastrointestinal diseases, produce a significant elevation in PRL release. A number of psychiatric drugs also cause elevations in PRL concentrations, including haloperidol and resperidol. In addition, antihypertensive agents, such as beta blockers and calcium channel blockers, and antihistamines, such as cimetidine and ranitidine, are associated with modest elevations in PRL. TSH measurements should be considered in patients suspected of a prolactinoma to rule out primary hypothyroidism, a thyroid condition associated with elevations in PRL. Imaging of the pituitary gland with computed tomography or magnetic resonance imaging is usually performed as part of the clinical work-up for a suspected prolactinoma. Most patients with PRL concentrations >200 μg/L have a PRL-secreting tumor; many large prolactinomas are associated with PRL concentrations of >1000 μg/L. Most patients with a prolactinoma fail to show a further increase in PRL after TRH stimulation; however, the same is true for most patients with hyperprolactinemia from other causes. Unless a pituitary tumor can be demonstrated by computed tomography or magnetic resonance imaging, the diagnosis of a PRL-secreting microadenoma (<10 mm in diameter) is one of exclusion. Because 50% of PRL-secreting microadenomas are too small to be seen using neuroradiological techniques, delineating the distinction between a small pituitary tumor, PRL-cell hyperplasia, and idiopathic hyperprolactinemia may not be possible without surgical intervention.

Finding an elevated PRL concentration in a patient with a pituitary tumor does not establish a cause-and-effect relationship. Usually a PRL concentration in excess of 200 ng/mL is sufficient evidence to strongly suspect a PRL-secreting pituitary tumor. However, "pseudoprolactinomas" do occur and are large nonsecretory tumors that press on the pituitary stalk, disrupting the normal inhibitory flow of dopamine from the hypothalamus, resulting in modest elevations in PRL concentrations (typically between 50 and 200 μg/L). It is particularly important to recognize this distinction when deciding on treatment, because PRL-secreting macroadenomas (>10 mm in diameter) usually decrease in size with medical therapy, but "pseudoprolactinomas" do not. (Even though PRL concentrations usually decrease with bromocriptine treatment, pseudoprolactinomas often continue to grow in size.) In patients with pituitary macroadenomas, a PRL concentration <200 μg/L usually indicates the presence of a pseudoprolactinoma, and a PRL concentration >500 μg/L suggests a true PRL-producing tumor. On occasion patients will present with macroprolactinemia, a condition associated with elevated circulatory concentrations of the polymeric forms of PRL with a molecular mass in excess of 100 kDa.

Polymeric forms of PRL lack biological activity; thus none of the sequelae associated with an elevated PRL concentration (sexual dysfunction and galactorrhea) are

present. In addition, macroprolactinemia is not associated with either negative or positive feedback effects at the concentration of the hypothalamus, and macroprolactin has not been found in pituitary tissue or cerebrospinal fluid. Thus macroprolactinemia appears confined to the vascular compartment and appears to be due to an atypical complexing of the different isoforms of PRL in the circulation. Macroprolactinemia, although not causative of symptoms associated with an elevated PRL, is troublesome for the clinician and laboratory in terms of interference in standard PRL immunoassays. In one report, almost 20% of patients who presented for a clinical work-up for prolactinoma had hyperprolactinemia attributable to the presence of macroprolactin. Although the prevalence of macroprolactinemia was approximately 1.5% in the population studied, the report suggested that macroprolactinemia is more common than previously realized. Thus clinical laboratories must have a mechanism in place to rule out the presence of a macroprolactinemia early in the work-up of the suspected prolactinoma patients.[122A] Measurement of the recovery of serum PRL following precipitation of the macroprolactin in the sample with polyethylene glycol (PEG) is the most common laboratory approach to look for the presence of macroprolactin.[125A] Gel-filtration chromatography has also been used to separate out the PRL isoforms, but the PEG approach is more practical and appears to effectively expose macroprolactinemia in patients without a pituitary prolactinoma in that PEG can precipitate out most of the isoforms not monomeric in size (>50 kDa).

Measurement of Prolactin

Before immunoassays for PRL became widely available, PRL concentrations were estimated using impractical bioassays based on the growth-promoting action of PRL using the pigeon crop sac or the rat mammary gland, both of which also measure effects of GH and human placental lactogen.[57,92] More sensitive and specific in vitro bioassays for PRL used a mitogenic responsive Nb2 cell line derived from a rat lymphoma.[123] Receptor assays have also been used for measuring PRL; in these assays, lactogenic activity is determined by the ability of specimens to inhibit the binding of radioiodinated hormone to membrane-bound receptors.[117] In general, bioassays and radioreceptor assays for PRL are too impractical, insensitive, and nonspecific for routine use; thus they have been restricted for evaluating PRL bioreactivity when immunoassay results appear to be at variance with the clinical effects of the hormone.

The early development of reliable immunoassays for PRL was hampered by extensive cross-reactivity of the antibodies used and the lack of purified human PRL calibrators. To minimize such problems, heterologous systems in which the hormones used for immunization and labeling were derived from different species were used.[57] As purified human PRL became more readily available, homologous competitive-binding immunoassays were developed for the specific determination of PRL in microliter volumes of serum or plasma specimens.[119] Initially, RIA was the predominant method for measuring PRL. These RIA methods used conventional liquid phase double-antibody techniques to separate antibody-bound and free fractions; others sped up the separation step by using a modified double-antibody approach (e.g., PEG-assisted double-antibody separation, solid phase-linked antibody, or magnetizable solid phase-linked second-antibody techniques).

Performance characteristics of PRL immunoassays varied from one procedure to another.[59] When selecting an RIA method, it was desirable that the method use reagents of human origin, have a wide analytical range linear from 5 to 200 µg/L, show a 50% displacement point in the upper normal reference interval (10 to 20 µg/L), and not be affected by GH concentrations.[6] Because most immunoassays for PRL have an upper limit of measurement of 200 µg/L, a 2× dilution should be performed with results in the 180 to 200 µg/L range and greater to produce an accurate result. Patients with a macroadenoma can have PRL concentrations in the thousands and could be missed if the sample is not diluted properly. The final and absolute concentration reported is an important determinant of the type of clinical management the patient will receive and whether surgical or medical therapy is indicated. For most PRL RIAs, the interlaboratory coefficient of variation ranges from about 5% to 10% at 50 µg/L; the detection limit, defined as the 95% confidence limit at the zero calibrator, is approximately 1 to 3 µg/L; and the cross-reactivity with GH <1%.

Two-site immunometric or "sandwich" assays that made use of two or more antibodies directed at different parts of the PRL molecule were next to be developed. As with other two-site IRMA assays, the capture antibody is attached to a solid phase separation system and the second or signal antibody is labeled with a detection molecule (e.g., radioisotope,[83] enzyme,[18,82,121] fluorophor,[63] or chemiluminescence tag[69]). In some assays, the capture antibody is attached to the wall of test tubes, plastic beads, microtiter plates, ferromagnetic particles, or glass-fiber paper. Other assays have used the strep-avidin approach that couples biotin to the signal antibody with avidin linked to a solid phase. Most of the current immunometric assays for PRL have been adapted to fully automated immunoassay systems. Compared with the older traditional RIA methods, these automated immunometric assays for PRL generally achieve lower detection limits (0.2 to 1.0 µg/L) and improved precision (interlaboratory coefficients of variation of <8% at all concentrations), and have superior specificity (<0.05% cross-reactivity with GH).

Comparison of PRL results yielded by different immunoassay methods, however, provides evidence of considerable variation. Some of these discrepancies relate to the molecular heterogeneity of the different PRL isoforms found in the circulation as previously discussed. All of the isoforms identified possess immunoreactivity, with the monomeric PRL representing more than 75% of the total, big PRL <20%, and big-big PRL <5%.[120] A glycosylated form of the monomeric hormone (G-PRL) predominates in the serum of normal subjects; in hyperprolactinemia and pregnancy,

the ratio of G-PRL to PRL decreases. In competitive immunoassay methods, some antisera do not recognize the high molecular weight variants and others, particularly at high PRL concentrations. Immunometric assays tend to give lower estimates of PRL concentration than do competitive immunoassays or bioassays and may not recognize some forms of the hormone. G-PRL, for example, is significantly underestimated in many immunoassays by 50% to 70%.

In view of the fluctuation in the proportion of PRL variants with different molecular masses and immunoreactivities, PRL procedures should be calibrated against reference materials with known international unit potency, such as the WHO first IRP 75/504, the second international standard (IS) 83/562, or the third IS 84/500 (http://www.nibsc.ac.uk). Without such calibration, PRL results expressed in mass units cannot be compared from assay to assay. Despite the heterogeneity of PRL, immunoassays correlate well with bioassays and remain the standard method of measurement in routine practice.

Specimen Collection and Storage

Serum is the specimen of choice for the PRL assay. No special handling procedures are necessary, and samples can be stored at 4 °C for 24 hours. Freezing is preferred when analysis is to be delayed a day or two for maintaining long-term stability. Specimens should be collected 3 to 4 hours after the subject has awakened, because PRL concentrations rise rapidly during sleep and peak in the early morning hours. Emotional stress, exercise, ambulation, and the ingestion of protein all produce a modest elevation in PRL concentrations; thus specimens should be collected after an overnight fast when the patient is resting. Because PRL is secreted episodically, multiple sampling techniques may be advantageous (e.g., pooling equal volumes of sera from specimens drawn at 6- to 18-minute intervals). Blood specimens can also be collected by finger puncture, spotted on filter paper, and stored in air-tight plastic bags. PRL in blood spots is stable for 1 week at room temperature.[10]

Reference Intervals

Representative values using an IRMA are as follows[125]:

		µg/L
Cord blood		45-539
Children		
Tanner stage		
1	Male	<10
	Female	3.6-12
2-3	Male	<6.1
	Female	2.6-18
4-5	Male	2.8-11
	Female	3.2-20
Adults	Male	3.0-14.7
	Female	3.8-23.0
Pregnancy, third trimester		95-473

Comments

Data on reference intervals for a large pediatric population have been published.[28] In view of PRL heterogeneity, there is a strong case for expressing assay results in international units rather than in mass units. Most reagent manufacturers supply a conversion factor for this purpose.

Corticotropin (Adrenocorticotropin) and Related Peptides

Corticotropin is a peptide hormone secreted by the adenohypophysis, one of the derivatives of pro-opiomelanocortin (POMC); it acts primarily on the adrenal cortex, stimulating its growth and the secretion of corticosteroids. Its production is increased during times of stress. It is also known as adrenocorticotropic hormone, ACTH, corticotrophin, adrenocorticotrophin, and adrenocorticotropin.

Biochemistry

Corticotropin and related peptides originate from a large precursor molecule of MW 31 kDa, called POMC. As shown in Figure 50-7, processing of POMC to smaller peptides takes place in both the anterior and intermediate lobes of the pituitary gland (the latter is vestigial in humans except during fetal life and at the end of pregnancy). In the anterior lobe of the pituitary gland, enzymes hydrolyze POMC to β-LPH and a 22-kDa fragment known as *pro-ACTH*. This latter peptide is further processed to ACTH (1-39, a peptide consisting of 39 amino acids) and to a 16-kDa peptide, pro-γ-melanotropin (pro-MSH). β-LPH in turn is cleaved to two smaller peptides, β-endorphin and γ-LPH. Both β-LPH and β-endorphin are released with ACTH from the anterior lobe of the pituitary gland, but only about one third of the β-LPH is converted to β-endorphin. In contrast the intermediate lobe (when present) fully processes β-LPH to β-endorphin, cleaving pro-α-melanotropin (MSH) to α-melanotropin (α-MSH), and splitting ACTH to α-MSH and a corticotropin-like intermediate-lobe peptide. These smaller peptides are found in the human fetus, but only trace amounts exist in the adult human pituitary gland. The changes observed in skin pigmentation in several endocrine diseases (e.g., with adrenal insufficiency) are most likely due to the α-MSH activity of excess ACTH.

In addition to β-endorphin, β-LPH contains the amino acid sequence of another endogenous opioid, *met-enkephalin*. However, this peptide is not the product of β-LPH breakdown, but rather arises from a precursor molecule known as *pro-enkephalin*. Pro-enkephalin is widely distributed in neurons throughout the brain and spinal cord. Some pro-enkephalin is found in the pituitary gland, but most is localized in the catecholamine-synthesizing cells of the adrenal medulla and is co-released with epinephrine and norepinephrine. In the medulla, pro-enkephalin gives rise to met-enkephalin (Tyr-Gle-Gle-Phe-Met) and leu-enkephalin (Tyr-Gle-Gle-Phe-Leu) and to larger opioid peptides. A third family of endogenous opioid peptides is derived from *prodynorphin*, a prohormone stored primarily in the poste-

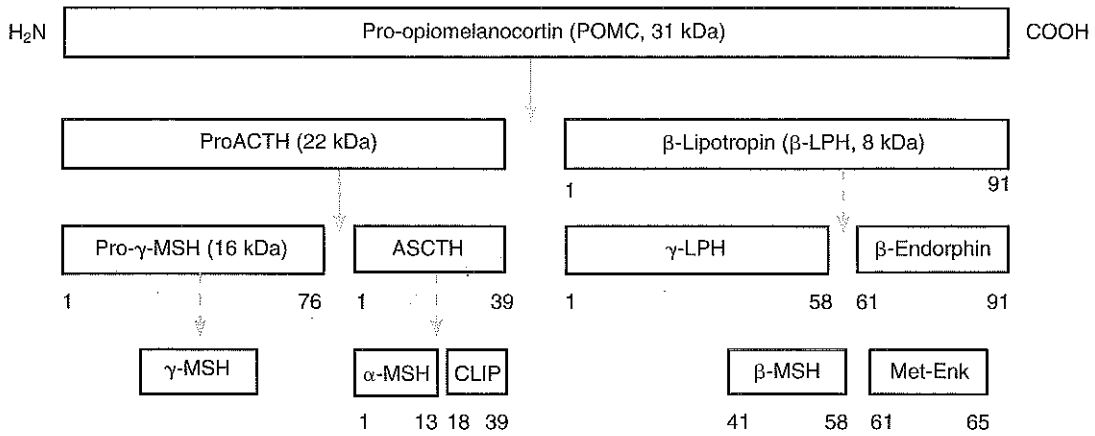

Figure 50-7 Diagrammatic representation of POMC and its precursor relationship to ACTH, β-LPH, α- and β-MSH, and the endorphins.

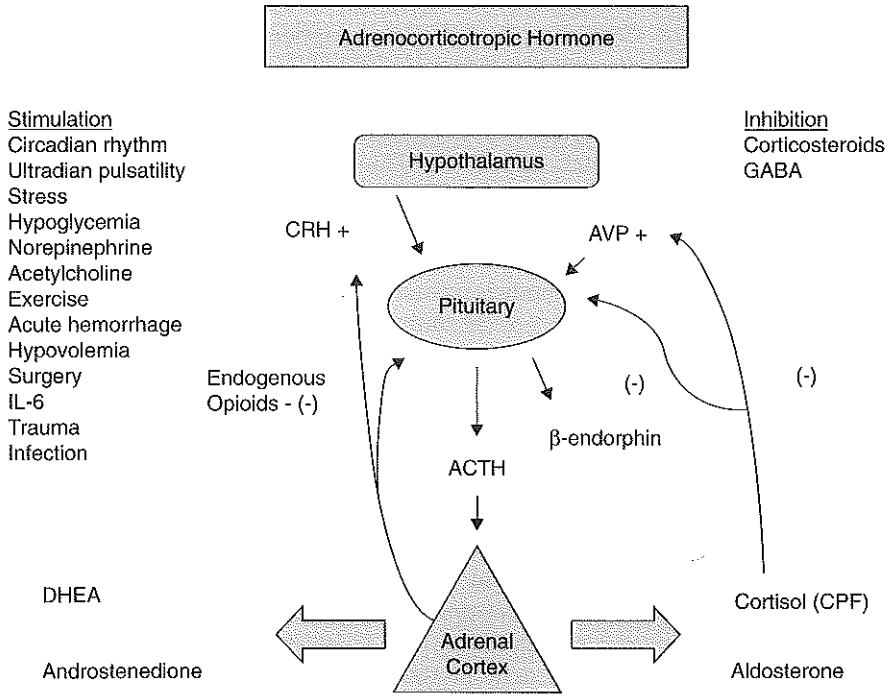

Figure 50-8 The regulatory feedback loop of the hypothalamic-pituitary-adrenal axis. CRH under the influence of neural factors and other modifiable factors that control its pulsatile and circadian secretion acts on the pituitary to produce hormone (ACTH). ACTH in turn stimulates the adrenal gland to form cortisol, aldosterone, dehydroepiandrosterone (DHEA), and androstenedione. Corticosteroids and gamma amino butyric acid (GABA) are inhibitory to CRH and ACTH release, and AVP stimulates ACTH release.

rior lobe of the pituitary gland where it is co-released with vasopressin.

Regulation of Adrenocorticotropin Secretion

Regulation of the secretion of ACTH is described in detail in Chapter 51 and is shown in Figure 50-8. Many variables affect the secretion of ACTH, which is both pulsatile and circadian in nature. Thus the regulation of pituitary secretion of ACTH by the hypothalamus and higher centers is complex. This complex control underscores the importance of the neuroendocrine regulation of stress homeostasis. Cortisol is the major negative feedback hormone for the tonic inhibition of CRH and ACTH release; however, endogenous opioids such as met-enkephalin and β-endorphin formed by the adrenal glands have a down regulatory effect on the hypothalamic-pituitary-ACTH axis as well.

Clinical Significance

Because ACTH synthesis originates from the POMC precursor peptide, its production by the pituitary is closely tied to the secretion of endogenous opiate peptides, such as β-endorphin. The physiological effects of endogenous opiates include (1) sedation, (2) an increased threshold of pain, and (3) autonomic regulation of respiration, blood pressure, and heart rate. These peptides are also involved in modifying endocrine responses to stress and water balance

and may play a role in the regulation of reproduction and the immune system. Gonadotropin secretion by the pituitary is under some form of inhibitory control by opioid peptides as evidenced by the effects of β-endorphin analogues on the pulse frequency and amplitude of pituitary LH release. In contrast, β-endorphin antagonists such as naloxone can elicit an increase in the amount and pattern of gonadotropin secretion. ACTH secretion is similarly down regulated by endogenous opioid peptides, and naloxone causes an increase in plasma ACTH concentrations. No diseases, however, have been clearly associated with disordered metabolism of opioid peptides, but changes in their plasma concentrations may accompany other disorders, such as Cushing's disease and depression (increased β-endorphin concentrations)[33] or pheochromocytoma (increased enkephalin concentrations).[136] Altered concentrations of opioids in cerebrospinal fluid may reflect disorders such as chronic pain syndromes, schizophrenia, and depression.

Measurement of ACTH

ACTH has been measured by bioassay, receptor assay, or immunoassay. Most bioassays are based on the effects of ACTH on adrenocortical cells (e.g., the stimulation of steroidogenesis or depletion of ascorbic acid). Responses are usually observed in the adrenal glands of hypophysectomized animals in situ or in isolated adrenal cells in vivo.[94] In general these bioassays are expensive and difficult to perform and are limited to research laboratories. Receptor assays use solubilized binding proteins obtained from normal or neoplastic adrenocortical cells.[74] Only biologically active ACTH is measured, and a 10-pg/mL detection limit has been reported in unextracted plasma. These assays have limited application in the clinical laboratory partly because of the complexity and lability of receptor preparations.

Binding assays that use specific ACTH antibodies are more common than either bioassays or receptor assays. In one of the earliest RIAs, ACTH in unextracted patient specimens competed with radioiodinated hormone for a limited number of antibody binding sites. After a 5- to 7-day incubation period, separation was achieved using either chromatoelectrophoresis or precipitation with talc.[15] Other competitive binding immunoassays have been described for ACTH; they differ in the choice of radiolabel tracer (^{125}I is preferred), separation system (e.g., charcoal adsorption, PEG, or second-antibody precipitation), antisera (e.g., N-terminal or C-terminal specificity), or the need to extract ACTH before assay.[91] Individual immunoassay components (anti-ACTH antisera and ACTH calibrators) and complete reagent test kits continue to be readily available commercially. Most use polyclonal antisera directed at a segment of the biologically active N-terminal portion of the molecule. As expected, these antisera react with intact ACTH (amino acids 1-39) and with ACTH fragments (amino acids 1-24) and precursor molecules, such as POMC and pro-ACTH.[133]

The concentration of ACTH in plasma is normally very low (about 5 to 80 pg/mL in morning specimens). Because most competitive RIAs use antibodies of modest affinity, such procedures that directly measure ACTH in unextracted plasma are usually unable to quantitate low or even low-normal concentrations with confidence (detection limit >15 pg/mL). Various approaches have been used to decrease the ACTH method lower limit of detection. For example, preliminary extraction of 1 to 5 mL of plasma (e.g., by adsorption of ACTH to glass particles, cation-exchange chromatography, and C18 Sep-Pak chromatography) concentrates the specimen and removes nonspecific plasma protein interferences that might otherwise inhibit antigen-antibody binding. Other enhancements include increasing the primary antibody incubation time to several days and using sequential addition of reagents (e.g., preincubate the patient specimen with antibody for 30 minutes before adding the tracer).[50] These maneuvers, however, often add to the complexity of ACTH assays and are less precise and more time consuming than other methods.

Immunometric assays for ACTH that use labeled monoclonal antibodies in noncompetitive formats have also been developed.[42] In these assays, two monoclonal antibodies are directed at different sites on the ACTH molecule (e.g., the N-terminal and C-terminal regions). In terms of assay detection limit, simplicity, and speed, these "two-site sandwich" immunometric assays can detect relatively low ACTH concentrations (1 to 4 pg/mL) with reasonable certainty and are able to distinguish true low from low-normal specimens.[139] Monoclonal immunometric assays also show improved analytical specificity for intact ACTH, but in some cases, they may be too specific and may fail to recognize biologically active and clinically relevant precursors and fragments.[104] Less specific ACTH immunoassays are sometimes used to detect the presence of these peptide fragments in patients with cancer-related syndromes (e.g., ectopic ACTH Cushing's syndrome); a two-site IRMA has also been developed for measuring ACTH precursors in plasma.[30] A direct (unextracted) immunoradiometric test kit for ACTH is commercially available that uses a polyclonal antibody–monoclonal antibody sandwich of the ACTH molecule. The monoclonal antibody is radiolabeled with ^{125}I for detection. A nonisotopic time-resolved immunofluorometric method has also been reported.[34] ACTH assays also have been developed on automated immunoassay platforms using immunochemiluminescence (ICMA)-based methods. These methods are much more precise than the manual methods (coefficients of variation [CVs] <8%) and provide more laboratories with the opportunity to measure ACTH. The enhanced sensitivity of the ICMA methods makes it possible to distinguish low-normal from genuinely depressed concentrations, thus the newer ACTH methods make it possible to measure ACTH at both low and high concentrations.

Numerical results from different ACTH immunoassays may be difficult to compare because of differences in calibration. At present, laboratories and manufacturers of commercial kits usually calibrate their assays against ACTH preparations obtained from research centers, such as human

purified ACTH 1-39 (MRC 74/555, 6.2 IU per 25 μg) supplied by the National Institute for Biological Standards and Control (United Kingdom) or synthetic ACTH 1-39 (4.71 IU per 50 μg) supplied by the United States National Hormone and Pituitary Program (NHPP; http://www.humc.edu/hormones/), which was formerly known as the National Pituitary Agency. For comparison purposes, the calibrators used in a particular assay system must be clearly defined.

Specimen Collection and Storage

Proper precautions must be taken in the collection, transportation, and storage of specimens. ACTH is easily oxidized, strongly adsorbs to glass surfaces, and can be rapidly degraded by plasma proteases into immunoreactive fragments during freezing and thawing of the specimen. Factors that influence plasma ACTH, such as prior administration of corticosteroids, time of day at which the specimen is taken (diurnal variation), and stress from a poorly performed venipuncture, must be taken into account. To minimize these problems, it is usually recommended that blood specimens be collected into prechilled polystyrene (plastic) tubes containing EDTA, immediately placed on ice, and centrifuged at 4 °C. Some laboratories also recommend the use of protease inhibitors, such as aprotinin (Trasylol). The supernatant is then transferred to another plastic tube and stored at −20 °C or colder. To protect the ACTH molecule further, antioxidants such as mercaptoethanol may also be used. Immediately before setting up the ACTH assay, frozen specimens should be thawed and centrifuged to remove any fibrin clots, which can interfere with the assay system.

Reference Intervals

Representative values using an IRMA are as follows:

REFERENCE INTERVALS—IRMA METHOD[125]

Adults	0800-0900 hr	8-25 ng/L
	2400 hr (supine)	<10 ng/L

Measurement of Endogenous Opioid Peptides

Beta-endorphin is a frequently measured opioid peptide. Immunoassay is the method of choice for the analysis of plasma β-endorphin. Both RIAs and direct IRMAs[51] have been developed for this purpose. Commercial reagent kits are widely available, and many commercial reference laboratories offer β-endorphin assays. The concentrations of β-endorphin are usually very low to undetectable in normal subjects, and it may be necessary to use extraction procedures to detect meaningful concentrations in plasma. The specificity of commercial antibodies for β-endorphin relative to β-LPH varies widely; in some immunoassays, 50% cross-reactivity is seen with β-LPH. With polyclonal antibodies, results may be spuriously high owing to cross-reactivity with serum immunoglobulin G (e.g., in patients with immunoglobulin G myeloma).[53]

The preferred specimen is plasma with EDTA as the anticoagulant. A typical adult reference interval for specimens collected between 6 AM and 10 AM is 16 to 48 pg/mL (5 to 30 pmol/L).[125]

The measurement of met-enkephalin in plasma is difficult because of its very short half-life (2.5 minutes at 37 °C). Even if blood is immediately chilled on ice and centrifuged under refrigeration, about 50% of the enkephalin is lost unless the specimen is collected with 23 mmol/L of citric acid.[1] Commercial kits for met-enkephalin measurements have been developed, and antienkephalin antibodies are available.

Gonadotropins (Follicle-Stimulating Hormone, Luteinizing Hormone)

Follicle-stimulating hormone (FSH) is synthesized in the adenohypophysis, and (1) stimulates the growth and maturation of ovarian follicles, (2) stimulates estrogen secretion, (3) promotes the endometrial changes characteristic of the first portion (proliferative phase) of the mammalian menstrual cycle, and (4) stimulates spermatogenesis in the male. It is also called *follitropin*. Luteinizing hormone (LH) is also synthesized in the adenohypophysis and acts with FSH to promote ovulation and secretion of androgens and progesterone. It instigates and maintains the second (secretory) portion of the mammalian estrus and menstrual cycle. In females it is concerned with corpus luteum formation, and in males it stimulates the development and functional activity of testicular Leydig cells. LH is also called *interstitial cell-stimulating hormone* and *lutropin*.

Biochemistry

The glycoprotein hormones of the pituitary (LH, FSH, and TSH) and of the placenta (chorionic gonadotropin [CG]; see Chapter 54) are composed of two peptide chains (usually referred to as α- and β-subunits), each with carbohydrate substituent groups attached. The carbohydrate moiety, which accounts for 15% to 31% of the molecular weight, includes fucose, mannose, galactose, glucosamine, galactosamine, and sialic acid. The α-subunits of these hormones are similar to one another and are interchangeable. For example, the hybrid molecule made up of the α-subunit of TSH and the β-subunit of LH possesses LH activity. The β-subunits display greater differences in amino acid sequences among the various hormones that confer hormonal and immunological specificity. Isolated α-subunits are devoid of biological activity. Isolated β-subunits may have slight intrinsic biological activity, but full activity is attained when α- and β-subunits are recombined. This suggests that the presence of both α- and β-subunits is important for specific receptor recognition, and that the β-subunit is responsible for eliciting the specific biological response. The availability of specific antisera for β-subunits has led to the development of RIA methods targeted for the specific measurements of these structurally similar glycoprotein hormones (see discussion of CG, Chapter 54).

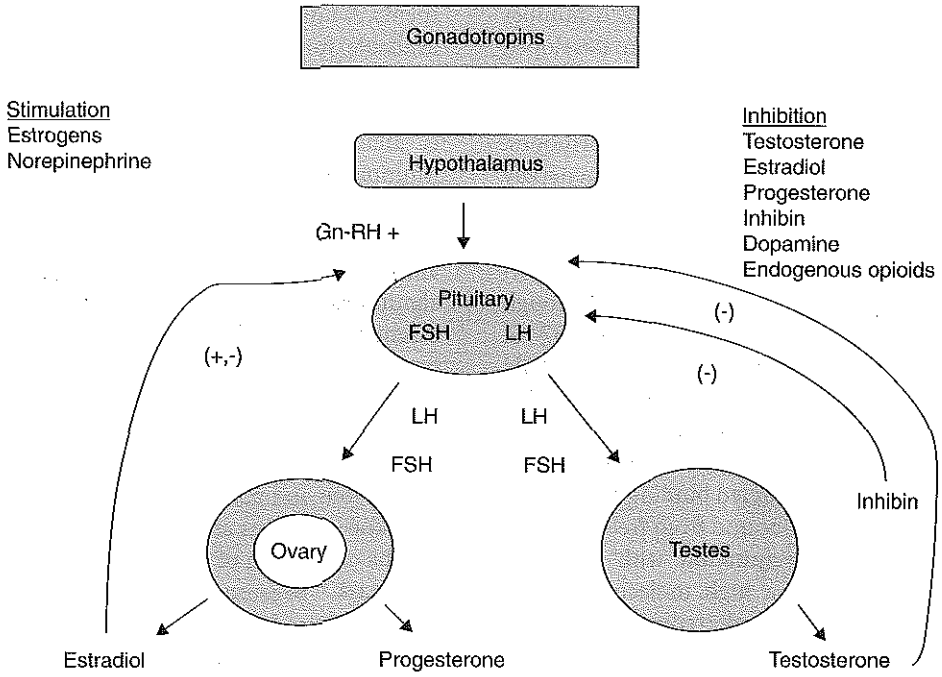

Figure 50-9 The regulatory feedback loop of the hypothalamic-pituitary-gonadal axis. Neural and sensory input from the brain elicits the release of Gn-RH. Gn-RH in turn stimulates the synthesis and release of the gonadotropins FSH and LH, which act on the gonads (ovary and testes) to elicit the ripening and ovulation of the ovary and steroidogenesis (estradiol and progesterone) in the female and spermatogenesis and testosterone production in the male. Inhibin formed by the ovaries and testes along with estradiol and testosterone negatively feeds back to the hypothalamic-pituitary axis to modulate Gn-RH, FSH, and LH release.

The gonadotropic cells of the anterior lobe of the pituitary gland secrete FSH (MW 30 kDa) and LH (MW 32 kDa). In males, LH has in the past been referred to as *interstitial cell–simulating hormone*. Because these two hormones control the functional activity of gonads, they are grouped together under the generic term *gonadotropins*. The regulation of gonadotropin secretion in males and females is shown in Figure 50-9. Pituitary gonadotropin secretion comes under the classic feedback system characteristic of higher centers of control. Estrogen and inhibin regulate LH and FSH secretion, respectively, in the female, and testosterone and inhibin regulate LH and FSH release in the male.

Physiological Action

In females, FSH stimulates the growth of ovarian follicles and, in the presence of LH, promotes secretion of estrogens by the maturing follicles. LH in females causes ovulation and release of the ovum from the ovarian follicle, which has previously ripened under the influence of FSH, and causes luteinization of the ruptured follicle to form the corpus luteum. The corpus luteum then secretes both progesterone and estradiol under the influence of pulsatile LH release. In males, FSH stimulates spermatogenesis by the germ cells in the testes, and LH is responsible for the production of testosterone by the Leydig cells of the testes.

Regulation and Clinical Significance

Regulation of LH and FSH secretion and its clinical significance in reproductive endocrinology are discussed in Chapter 53.

Measurement of Luteinizing Hormone, Follicle-Stimulating Hormone, and Free α-Subunits

Methods for assaying gonadotropins have evolved from bioassays and receptor assays to immunoassays that make use of radioactive and nonisotopic labels. Early in vivo bioassays were based on the direct effects of gonadotropins on the rat ovary, such as depletion of ascorbic acid (by LH) or augmentation of ovarian weight (by FSH).[76] These methods were insensitive and lacked the necessary specificity and precision to measure LH and FSH in small volumes of serum; consequently, they were mainly applied to the assay of urine concentrates. Most bioassays developed in recent years for gonadotropins have gravitated to in vitro techniques. The LH method, for example, measures testosterone synthesis by dispersed rat Leydig cells in response to gonadotropin stimulation.[35] Cultured rat granulosa cells secreting estradiol are used to measure FSH activity in serum.[61] Bioassay methods are still in use today but are primarily tools used in research laboratories investigating the mechanism of action of gonadotropins. Immunoassays have replaced bioassays and receptor assays for gonadotropin

measurements in the routine clinical laboratory. A number of different immunoassay methods have been developed for determining FSH and LH in blood and urine, and reliable commercial kits are widely available.[112] RIA steps are similar to those described for other protein hormones. Assays performed by sequential saturation analysis generally give better sensitivity at low hormone concentrations than equilibrium type assays. In a typical delayed addition procedure, specimens, calibrators, and controls are incubated with rabbit antisera for 5 to 7 hours at 4 °C, although some assays require incubation for only 30 minutes at 37 °C. During this time, a significant proportion of LH or FSH becomes bound to the relevant antibody. ^{125}Iodine-labeled hormone is then added, and during a second incubation period (e.g., 16 to 24 hours at 4 °C or 1 hour at room temperature), the label binds to unoccupied binding sites on the antibody. Separation of antibody-bound from free hormone is usually accomplished by precipitation with a second (double) antibody. Inclusion of a high molecular weight polymer, such as PEG, can significantly reduce the incubation time for complete precipitation. Alternatively the second antibody can be coupled to a solid phase support that is centrifuged or sedimented with gravitation. The concentration of gonadotropins in the sample is determined by comparing radioactivity in the specimen tubes with the calibration curve prepared with known concentrations of the relevant gonadotropin. RIAs for LH and FSH are capable of detecting hormone concentrations to a sensitivity of about 1.0 and 0.5 IU/L, respectively. For specimens containing 5 IU/L or more of FSH or LH, between-run CVs average 5% to 10%.[13]

A small number of methods allow for simultaneous determination of FSH and LH in a single assay tube. Double-label RIAs using ^{57}Co-labeled LH and ^{125}I-labeled FSH as tracers are available as commercial kits. Following separation, each radioisotope is determined in the bound fraction by dual isotope counting or by repeat counting. A simultaneous immunofluorometric assay of LH and FSH, based on the use of the fluorescent lanthanides Eu^{3+} and Tb^{3+}, has also been described; each is detected with a time-resolved fluorometer.[54]

The antibodies used in the older RIAs for LH and FSH cross-reacted with each other and with structurally similar glycoprotein hormones, such as TSH and hCG. Assay specificity significantly improved when antisera were produced against the purified beta subunits of both LH and FSH. Currently, most RIAs for FSH show <1% cross-reactivity with LH, TSH, or hCG, or with their free α- or β-chains. In contrast, some RIAs for LH do show cross-reactivity with hCG (10% to 25%), such that LH estimates are invalid in pregnant women or individuals with hCG-secreting tumors.[13] Interference from high blood concentrations of TSH in untreated hypothyroid patients can also produce elevations in LH concentrations.

The introduction of two-site immunometric assays significantly improved the method for gonadotropin measurements. A number of LH and FSH "sandwich" assays became available for manual and automated instrument applications. In some commercial kits, the first antibody is immobilized on test tubes or plastic beads; in others, the antibody is attached to magnetic particles or glass-fiber paper. Multiple signal molecules are associated with the second antibody, including radioisotopes, enzymes,[43,75] fluorophors,[68] and chemiluminescent[79,116] molecules. The analytical advantages of these immunometric assays are significant. For example, hCG interference in LH assays has essentially been eliminated (<0.008% cross-reactivity), better assay precision has resulted (between-assay CVs of <10%), and improvements in assay sensitivity have been realized (detection limits of <0.2 IU/L).[5,13,115] The latter are especially important for use in the evaluation of prepubertal children and patients with hypothalamic disorders when LH concentrations are barely detectable.

The calibration of gonadotropin hormone assays is a difficult task,[24] because producing calibrators that are identical to the analytes found in clinical specimens is confounded by the fact that LH and FSH are not single chemical entities but rather are mixtures of closely related compounds. The earliest reference material used for this purpose was the second IRP for Human Menopausal Gonadotropins. This material was prepared from the urine of postmenopausal women and contained high concentrations of LH and FSH. Because of alterations during metabolism and excretion, however, this urinary calibrator is not appropriate for serum measurements and has been replaced by material derived from the human pituitary gland. Partially purified pituitary extracts, such as the first and second IRPs for FSH and/or LH, were available for many years but have recently been replaced by highly purified pituitary preparations that have high biological potency and low potential for contamination with cross-reacting glycoproteins and their subunits (Table 50-3). Most manufacturers of immunoassay kits for LH and FSH use one or more pituitary reference materials for standardizing their working calibrators. Recombinant gonadotropin calibrators are now available (Table 50-3) that are expected to obviate the problems associated with reference materials isolated from pituitary glands.

Despite enormous improvements in assay design and calibration, discrepancies in results are still obtained when using different immunoassay systems (notably those for LH)[60,129,133]; results can differ by more than 50% even when calibrated with the same reference preparation. The most likely explanation lies with the epitope specificity of the antibodies used in each method. In addition, many glycosylation isoforms exist in patient specimens, and different assays may recognize them differently depending on the antibodies used.[55] In the case of LH, immunometric assays that use monoclonal antibodies give considerably lower values than RIAs that use polyclonal antibodies. This difference is partly a result of the greater specificity of the monoclonal antibodies, which recognize only a subset of LH isoforms and epitopes. Other factors, however, also contribute to method-

dependent bias, such as differences in calibration procedures and assay matrix.

Several immunoassays have been described for quantifying the free α-subunit of pituitary glycoprotein hormones in serum. As expected, monoclonal antibody–based IRMAs of free α-subunits are more sensitive and specific than are conventional polyclonal RIAs. For example, the free α-subunit IRMA described by Grover and colleagues[49] showed negligible cross-reactivity with intact pituitary glycoprotein hormones (<0.001%) and had adequate sensitivity to detect these subunits in normal nonpregnant individuals and in patients with hormone-secreting tumors (detection limit ~10 ng/L).

Specimen Collection and Storage

Serum is the preferred specimen for gonadotropin measurements; hemolyzed, lipemic, or icteric specimens should not be used. Both hormones are stable for 8 days at room temperature and for 2 weeks at 4 °C; for longer periods, the serum specimen should be stored frozen at or below −20 °C. Because of episodic, circadian, and cyclic variations in the secretion of gonadotropins, a meaningful clinical evaluation of these hormones may require determinations in pooled blood specimens, multiple serial blood specimens, or timed urine specimens. Urine specimens should not contain preservatives; storage at or below −20 °C is recommended.

Reference Intervals

Expected values in serum using a sensitive ("third-generation") immunochemiluminometric assay are as follows[125]:

	LH (IU/L)	FSH (IU/L)
Males, 23-70 yr	1.2-7.8	1.4-15.4
Females		
Follicular phase	1.7-15.0	1.4-9.9
Midcycle peak	21.9-56.6	0.2-17.2
Luteal phase	0.6-16.3	1.1-9.2
Postmenopausal	14.2-52.3	19.3-100.6

	LH (mIU/hr)	FSH (mIU/hr)
Prepubertal	3-97	10-160
Pubertal	20-1800	18-1330
Adult female	190-3350	120-1490
Adult male	550-2500	190-1700

Measurement of Urinary Gonadotropins

Clinically, the pulsatile and episodic release of gonadotropins make a single blood concentration of FSH or LH difficult to interpret. In normal adults, the concentrations of gonadotropins in blood, particularly LH, have been known to

differ as much as threefold between samples taken from the same individual 20 minutes apart. In addition, the concentrations in blood with most immunoassays for FSH or LH can often reach the sensitivity limits of the blood assay in normal adults. In the prepubertal child, most blood assays cannot measure normal concentrations because of the low concentration usually encountered in the prepubertal period.

To prevent the problems associated with inadequate detection limits with most blood gonadotropin assays in children and to minimize the episodic secretion of FSH or LH, urine assays have become popular as a means of concentrating the urine sample to improve the detection limits and to integrate the pulsatility of secretion by collecting a urine specimen over a 3-hour period.[112] The kidney essentially integrates the pulsatile secretion over that time period, and the urine can be concentrated eightyfold using an acetone precipitation method to extract the gonadotropins from urine thereby enhancing the sensitivity of the method. Many pediatric endocrinologists favor the urine assay when working up young patients who are suspected of having a pubertal disorder of gonadotropin secretion. Consequently the concentrations of urine FSH and LH are easily detectable in normal prepubertal children when compared with the undetectable concentrations observed in these same normal children when using a blood assay for gonadotropins.

Clinically the measurement of urine FSH and LH using a timed collection (usually 3 hours) allows for integration of the marked pulsatility that occurs with gonadotropin secretion, improves method sensitivity (fiftyfold decrease in detection limit over the serum method), and facilitates the measurement of gonadotropins in young children suspected of a gonadotropin disorder or to test for constitutional delay in adolescence during the latter transition period of puberty.

THYROTROPIN

Thyrotropin is a glycoprotein hormone synthesized in the adenohypophysis that promotes the growth of, sustains, and stimulates the hormonal secretion of the thyroid gland. It is also called thyroid-stimulating hormone (TSH).

Biochemistry

With a molecular weight of 26.6 kDa, TSH is secreted by the thyrotroph cells of the anterior lobe of the pituitary gland. TSH is a heterodimer, glycoprotein hormone consists of two noncovalently linked α- and β-subunits with the α-subunit chemically similar to the α- subunits of LH, FSH, and hCG. TSH stimulates the growth and vascularity of the thyroid gland; stimulates the growth of thyroid follicular cells; and promotes a number of the steps in thyroid hormone synthesis, including the uptake of iodine, organification of iodine on to tyrosine, the coupling of tyrosines, and the proteolytic release of stored thyroid hormone from thyroglobulin stores.

Regulation, Clinical Significance, and Methodology

The regulation of TSH secretion, its clinical significance, and methods for determining TSH are discussed in detail in Chapter 52.

ASSESSMENT OF ANTERIOR PITUITARY LOBE RESERVE

Evaluation of endocrine function is an important part of the management of patients with pituitary tumors.[14,22] Detection of hormone deficiencies before and after treatment and recognition of hormone-producing tumors are the two objectives of testing of pituitary function in patients with pituitary tumors.[32]

The assessment of anterior and posterior pituitary lobe function in patients with pituitary tumors is important in the identification of clinically significant hormone deficiency states caused by the tumor itself and for the reevaluation of patients after pituitary surgery or irradiation to detect hormone deficiencies that occur as a result of invasive treatment. Testing of pituitary function is usually performed under basal conditions but can be performed under provocative conditions to bring out subtle or mild deficiencies that are observed with disorders of the adrenal gland, thyroid, or gonads. Evaluation of pituitary reserve for GH or PRL is usually unnecessary in adult patients because deficiencies of these hormones are not believed to be clinically important.

The lowered detection limits of the newer two-site immunoassays for the measurement of pituitary hormones now make it possible to distinguish an abnormally low value from the lower end of the normal reference interval. Although assessment of a particular aspect of pituitary function should also include clinical signs and symptoms of hormone deficiency and the measurement of hormones secreted by the pertinent endocrine gland (e.g., T_4, cortisol, and testosterone), the newer, ultrasensitive assays for TSH, FSH, LH, and ACTH allow for an accurate distinction of a true low result from low normal. A scheme for testing of pituitary reserve is listed in Box 50-6.

BOX 50-6 Method of Assessment of Pituitary Reserve

A. Before Pituitary Surgery
- Adrenal glands: measurement of morning serum cortisol concentration or cosyntropin stimulation test
- Thyroid gland: ultrasensitive determination of TSH
- Gonads: sex hormone determinations (estradiol in women and testosterone in men) and gonadotropins

B. Shortly After Pituitary Surgery (2 to 4 days After Surgery)
- Adrenal glands: morning serum cortisol concentration
- Thyroid gland: deferred
- Gonads: deferred

C. One Month After Pituitary Surgery
- Adrenal glands: cosyntropin stimulation test
- Thyroid gland: ultrasensitive determination of TSH concentration
- Gonads: sex hormone determinations (estradiol in women and testosterone in men)

TSH, Thyroid-stimulating hormone.

Hypothalamic-Pituitary-Adrenal Axis

A normal morning serum cortisol concentration is usually adequate evidence that the hypothalamic-pituitary-adrenal axis is intact and functioning properly. On occasion, however, the *Synacthen stimulation test* is used when the morning cortisol results are low or equivocal (<5 μg/dL) or when there is a strong clinical suspicion of adrenal insufficiency (see Table 51-1). This provocative test is performed by obtaining a baseline blood specimen for cortisol followed by the intravenous (IV) administration of 250 μg of Synacthen (a potent analogue of ACTH). Specimens for cortisol are then obtained at 30 and 60 minutes after IV administration of the synthetic ACTH. A peak value for plasma cortisol of >18 μg/dL is considered a normal response to ACTH administration.

Results of tests of the entire hypothalamic-pituitary-adrenal axis, such as the *insulin tolerance test* (also called the *insulin-induced hypoglycemia stimulation test;* see Box 50-3), occasionally are abnormal in patients who have a normal morning cortisol concentration, a normal response to exogenous ACTH, and no signs of adrenal insufficiency. Although an abnormality in these sensitive tests suggests some diminution of ACTH reserve, the clinical significance of such impairment in this setting is not clear. These tests should be reserved for patients who are strongly suspected of having adrenal insufficiency or whose morning cortisol concentration or response to ACTH has been found to be abnormal. Standard protocols for the performance and interpretation of these tests have been published. These tests involve some patient risk and discomfort and should be performed only under the direct supervision of an experienced physician.

Measurement of ACTH in blood collected either at baseline or after stimulation with insulin adds little to the utility of the above tests and is not generally recommended. In fact, in patients who have undergone pituitary surgery, it takes some time before the cortisol negative feedback loop to ACTH secretion is normalized. ACTH and cortisol measurements after administration of CRH are potentially a direct test of pituitary ACTH reserve. However, the insulin-induced hypoglycemia test is currently the definitive test of ACTH and/or cortisol reserve. This test, however, is contraindicated in patients with a history of coronary heart disease, seizure disorder, and general debility.

Hypothalamic-Pituitary-Thyroid Axis

When the serum free thyroxine concentration (FT_4) or ultrasensitive TSH result is normal, the hypothalamic-pituitary-thyroid axis is assumed to be intact. If primary hypothyroidism is suspected clinically, however, a single measurement of a basal TSH concentration may be sufficient to confirm the diagnosis. In patients with a history of pituitary disease and secondary hypothyroidism, the serum TSH concentration is frequently normal; thus in this situation, an FT_4 concentration is the better test to gauge normality of the hypothalamic-pituitary-thyroid axis. On occasion a TRH *stimulation test* is used to distinguish hypothalamic dysfunction from pituitary disease. This test is accomplished by drawing a blood specimen for measurement of baseline TSH concentrations, administering 500 μg of TRH intravenously, and collecting additional specimens for TSH measurements at 30, 45, and 60 minutes after IV injection. A normal response to TRH is a fivefold to tenfold increase in the serum TSH concentrations within 60 minutes after TRH administration. An impaired response in a patient with a low serum FT_4 concentration indicates a pituitary abnormality, whereas a delayed peak (at 45 or 60 minutes) suggests hypothalamic dysfunction. A blunted response is observed in patients with hyperthyroidism. With the availability of better third-generation tests for TSH (see Chapter 52), the TRH stimulation test is now rarely used.

Hypothalamic-Pituitary-Gonadal Axis

History and physical examination are extremely helpful in evaluating the status of the hypothalamic-pituitary-gonadal axis, particularly in women during their reproductive years.[3,81] Normal menstrual cycles are usually indicative of an intact hypothalamic-pituitary-gonadal axis in reproductive-age women. Baseline laboratory assessment for hypothalamic-pituitary-gonadal dysregulation should include measurement of serum gonadotropins (LH and FSH) and sex steroids (estradiol in females and testosterone in males). Provocative testing of this axis with Gn-RH and measurements of FSH and LH (Box 50-7) are useful in selected patients. These tests, however, can be unreliable in differentiating pituitary disorders from hypothalamic

BOX 50-7 Protocol for the Gonadotropin-Releasing Hormone (Gn-RH) Stimulation Test for Luteinizing Hormone (LH) and Follicle-Stimulating Hormone (FSH) Reserve

Rationale The hypothalamic releasing hormone Gn-RH stimulates release of both LH and FSH in normal individuals. Subnormal responses are seen in some patients with pituitary or hypothalamic disorders. However, the magnitude of LH and FSH response to Gn-RH is usually predictable from the basal LH and FSH concentrations. This test may be useful in patients in whom the clinical picture and basal gonadotropin measurements are inconclusive.

Procedure The test may be performed without regard for previous feeding or time of day. After baseline specimens are obtained for LH or FSH determination, or both, 100 μg Gn-RH is given intravenously. Samples for LH or FSH determination, or both, should be drawn every 15 to 30 minutes for 1 to 2 hours.

Interpretation LH response should increase by threefold to tenfold. The FSH response is of lesser magnitude (usually a 1.5- to 3-fold increase). The peak responses for both LH and FSH occur between 15 and 30 minutes. Patients with pituitary disorders may have normal, diminished, or absent responses. In patients with hypothalamic disorders, the response may be exaggerated, normal, diminished, or absent.

dysfunction; thus the physician is usually dependent on an accurate determination of gonadotropins and sex steroids along with clinical judgment.

Preoperative Endocrine Testing: A Simple Approach

Initial Assessment

Pituitary reserve is almost never compromised in patients with small pituitary tumors, so testing is usually limited to patients with large tumors or specific clinical indications (see Box 50-6, *A*). For most patients with large pituitary tumors, in addition to history and physical examination, an adequate evaluation of endocrine function before surgery can be performed based on laboratory measurements of serum PRL, TSH, LH, FSH, sex steroids (testosterone in males and estradiol in females), serum sodium, and results of a morning serum cortisol or ACTH stimulation test.

After Pituitary Surgery

The optimum time for retesting endocrine function after pituitary surgery is not generally known (see Box 50-6, *B*). At the M.S. Hershey Medical Center (Hershey, Pa.), the following protocol is used (Figure 50-10):

"Stress" steroid coverage with hydrocortisone is administered immediately before, during, and after surgery. If adrenal function is normal before surgery, steroid coverage is usually stopped on the second or third postoperative day and a morning blood sample for plasma cortisol concentration is obtained 24 hours later. If the morning plasma cortisol concentration is 5 μg/dL or less, ACTH deficiency is likely and steroid coverage is reinstituted and continued after discharge from the hospital. If the plasma cortisol concentration is 10 μg/dL or greater, the hypothalamic-pituitary-adrenal axis is presumed to be normal and steroid coverage is no longer mandated. Patients with a morning plasma cortisol concentration between 5 and 10 μg/dL should either have normal adrenal function confirmed with provocative testing (i.e. metyrapone test) or should be started back on hydrocortisone coverage.

Follow-Up Testing After Pituitary Surgery

It is advisable to wait until 1 month after surgery to evaluate thyroid function (measurement of TSH concentration) and gonadal function (measurement of testosterone concentration in males and estradiol concentration in females; see Box 50-6, *C*). Early treatment of thyroid and gonadal deficiencies is not critical, and misleading test results might be obtained in the early postoperative period. Adrenal function should be reassessed with an ACTH stimulation test 1 month after surgery, even if pituitary function was subnormal soon after surgery; ACTH deficiency after pituitary surgery is often transient. Periodic clinical follow-up and laboratory assessment should be tailored to the individual patient's circumstances.

After pituitary irradiation, patients should be evaluated every six months with an FT_4 and TSH measurement, sex steroid determination, and ACTH stimulation testing.

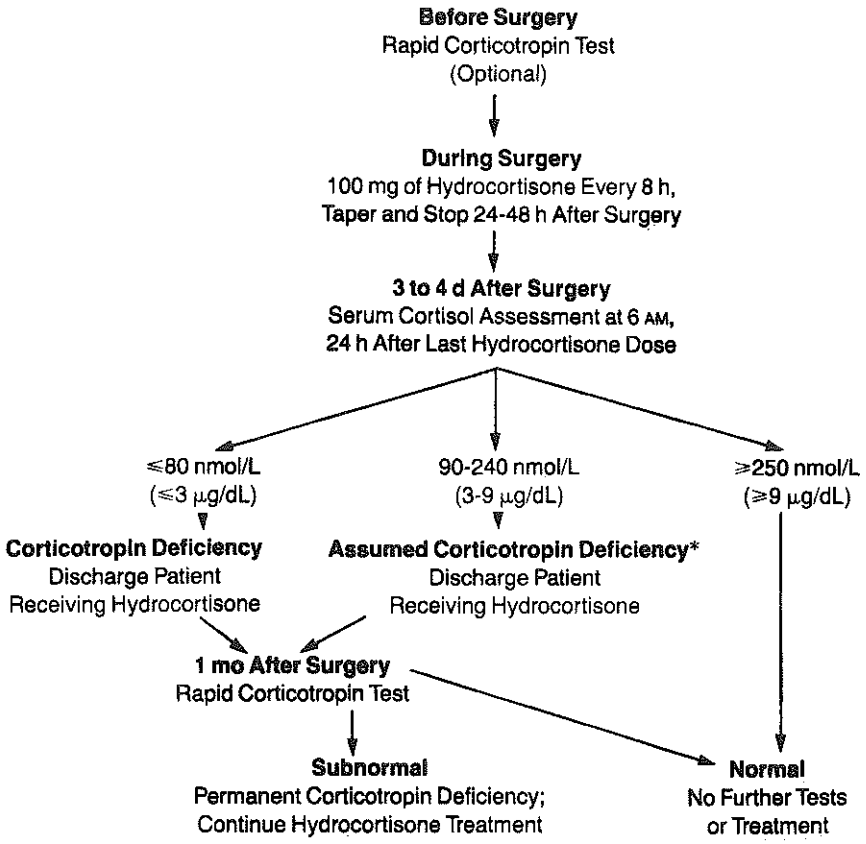

Figure 50-10 Algorithm for evaluation of the hypothalamic-pituitary-adrenal axis after transsphenoidal pituitary surgery. *(From Watts NB, Tindall GT. Rapid assessment of corticotropin reserve after pituitary surgery. JAMA 1988;259:708-11. Copyright 1988, American Medical Association. Used with permission.)*

NEUROHYPOPHYSIS

The neurohypophyseal system is composed of neural tissue and neurons of the supraoptic and paraventricular nuclei of the hypothalamus. These neurons are located in and travel through the median eminence and pituitary stalk, with the nerve endings projecting to the posterior lobe of the pituitary gland. The cell bodies of these neurons synthesize and secrete *oxytocin* and arginine vasopressin (AVP); the latter is also called *antidiuretic hormone (ADH)*. Oxytocin and AVP are nonapeptides (MW 1080 Da) consisting of a cyclic hexapeptide and a three–amino acid side chain. Most mammals secrete vasopressin and oxytocin, with the exception of the pig and hippopotamus, in which lysine vasopressin (contains lysine rather than arginine in position 8) is released. The structure of oxytocin is similar to that of AVP (Figure 50-11) but with isoleucine rather than phenylalanine at position 3 and leucine instead of arginine at position 8.

ARGININE VASOPRESSIN

AVP is formed by neuronal cells of hypothalamic nuclei and stored in the neurohypophysis. In humans, it contains arginine at position 8. (In pigs, lysine is found at position 8.) AVP stimulates contraction of the muscles of capillaries and arterioles, raising blood pressure; promotes contraction of the intestinal musculature, increasing peristalsis; exerts contractile influence on the uterus; and has a specific effect on the epithelial cells of renal collecting tubules, augmenting resorption of water independently of solutes to cause concentration of urine and dilution of blood serum. Its rate of secretion is regulated chiefly by the osmolarity of the plasma.

Biochemistry

AVP is synthesized as part of a large precursor molecule (preprovasopressin) in conjunction with a specific neurophysin-binding protein; the latter serves as a carrier protein for it during axonal transport and storage. Oxytocin is also synthesized as part of a preprohormone along with a separate neurophysin-binding protein. These molecular complexes are packaged into secretory granules that migrate down the nerve axons for 12 to 14 hours before reaching the posterior pituitary lobe for storage. Release of the neurohypophyseal hormones into the portal circulation occurs via calcium-dependent exocytosis on nerve cell stimulation. When a stimulus for secretion of either vasopressin or oxytocin occurs, the stimulus acts on the appropriate magnicellular cell body in the hypothalamus, sending an action potential down the long axon to the posterior pituitary, causing an influx of calcium and the release of hormone from neurosecretory granules. At the physiological pH of plasma, AVP and oxytocin circulate mainly in unbound forms.

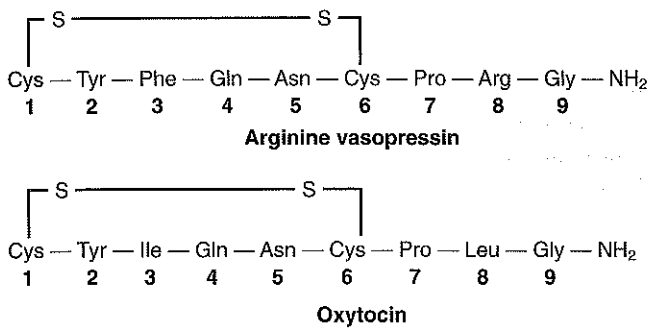

Figure 50-11 The amino acid sequence of AVP and oxytocin.

Regulation of Secretion

The tonicity (osmolality) of blood falls largely under direct control of vasopressin secretion. Osmoreceptors located in cell bodies in or near the magnicellular nuclei of the hypothalamus respond to changes in plasma osmolality. As little as a 2% increase in extracellular fluid osmolality can cause shrinkage of osmoreceptor cells with stimulation of AVP release from the posterior pituitary lobe (Figure 50-12). A plasma osmolality above 280 mOsm/kg is considered the osmotic threshold for AVP release.

Besides the osmoreceptor mechanism of vasopressin release, the physiological regulation of vasopressin secretion also involves a pressure-volume mechanism that is distinct from the osmotic sensor. AVP release is regulated by baroreceptors that respond to alterations in blood volume. For example, a reduction in plasma volume or arterial pressure,

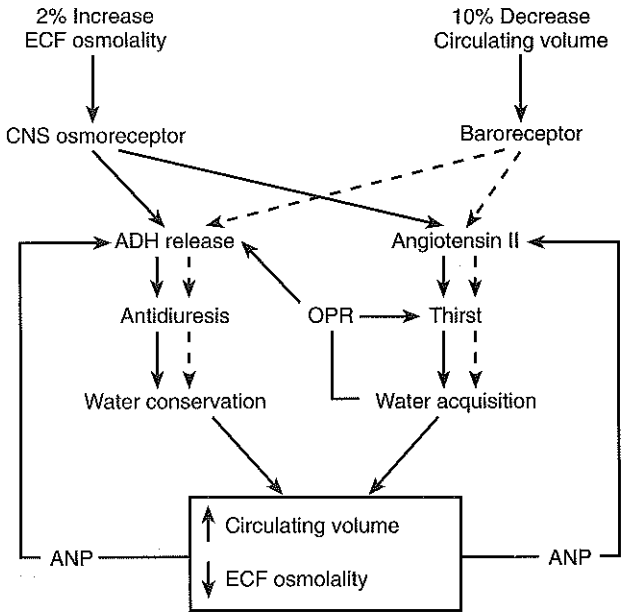

Figure 50-12 Key elements in water homeostasis. *Solid lines* indicate osmotically stimulated pathways, and *dashed lines* indicate volume-stimulated pathways. The *dotted lines* indicate negative feedback pathways. Abbreviations: *ANP*, atrial natriuretic peptide; *AVP*, arginine vasopressin; *CNS*, central nervous system; *ECF*, extracellular fluid; *OPR*, oropharyngeal reflex. *(From Reeves W, Andreoli T. The posterior pituitary and water metabolism. In: Wilson JD, Foster DW, eds. Williams textbook of endocrinology, 8th ed. Philadelphia: WB Saunders Co, 1992:312.)*

or both, stimulates vasopressin secretion. Other nonosmotic stimuli for AVP release include pain, stress, sleep, exercise, and chemical agents such as catecholamines, angiotensin II, opiates, prostaglandins, anesthetics, nicotine, and barbiturates. An increase in plasma volume or a decrease in plasma osmolality was previously thought to inhibit the release of AVP directly. It now seems likely that atrial natriuretic peptide provides some negative feedback for vasopressin release. Agents such as alcohol, phenytoin, and glucocorticoids can inhibit vasopressin release, leading to a water diuresis and physiological dehydration.

The thirst center is regulated by many of the same factors that determine AVP release. This center has a higher set point than the osmoreceptors and responds to osmolalities above 290 mOsm/kg. Responses involving AVP, thirst, and the kidney are coordinated in a complex scheme to maintain plasma osmolality in healthy individuals within a narrow range (284 to 295 mOsm/kg).

Physiological Actions

The major physiological function of vasopressin is the control of water homeostasis at the concentration of the kidney through the regulation of water permeability in the collecting tubules and ascending limb of Henle's loop (see Chapter 45). These effects, which are mediated through the adenylate cyclase system, allow the kidney to reabsorb water and concentrate urine. A further action of AVP is expressed by the "pressin" part of its name.[44] When released in sufficient quantity, AVP induces a generalized vasoconstriction that leads to a rise in arterial blood pressure. AVP is believed to play an important role in the maintenance of arterial blood pressure during blood loss. Release of vasopressin into the pituitary portal system also augments the action of CRH in stimulating the release of ACTH from the adenohypophysis. However, AVP does not appear to affect the release of other anterior pituitary hormones.

Clinical Significance

Disorders of AVP activity have been divided into hypofunction (diabetes insipidus) and hyperfunction (syndrome of inappropriate antidiuretic hormone secretion [SIADH]).

Polyuric States

Deficient production or action of vasopressin results in polyuria caused by the failure of the renal tubules to reabsorb solute-free water.[9] Under normal circumstances, urine output is largely dependent on fluid intake; thus an arbitrary limit for normal urine output cannot be defined. When urine output is >2.5 L/day, an investigation is usually indicated; with complete deficiency of AVP, urine output may approach 1 L/hr. If the thirst response is normal, increased ingestion of fluid (polydipsia) will follow. If access to water is not restricted, plasma osmolality and serum electrolytes will usually remain normal.

Polyuric states are divided into three main categories: (1) deficient AVP production (hypothalamic diabetes insipidus [HDI]), (2) deficient AVP action on the kidney (nephrogenic diabetes insipidus [NDI]), and (3) excessive water intake (psychogenic polydipsia). An osmotic diuresis may also produce polyuria and polydipsia. Uncontrolled diabetes mellitus with a high glucose load to the kidney is a common cause of an osmotic diuresis.

Hypothalamic Diabetes Insipidus. This is also called *neurogenic, central,* or *cranial diabetes insipidus.* HDI is caused by a failure of the pituitary gland to secrete normal amounts of AVP in response to osmoregulatory factors. Increased fluid intake promoted by thirst mechanisms prevents severe dehydration. When the thirst center is also abnormal, severe dehydration can occur. Destruction of 80% of vasopressin-secreting neurons is required to produce HDI; injury to the neurohypophysis may cause a transient diabetes insipidus. The incidence of HDI is about 1 in 25,000 people. In 30% of patients, HDI occurs without apparent cause; other cases are associated with neoplastic diseases, neurological surgery, head trauma, ischemic or hypoxic disorders, granulomatous diseases, infections, or autoimmune disorders. A hereditary form of the disorder is transmitted as an autosomal dominant trait, and the vasopressin gene defect responsible for this disorder has been identified. The genetic abnormality has been described at the concentration of the preprohormone for vasopressin, preventing normal cleavage of the signal peptide at the carboxy terminus of preprovasopressin. Although rare, diabetes insipidus can present in pregnancy as a result of high circulating activities of the enzyme cysteine aminopeptidase (vasopressinase) that inactivates vasopressin. The etiology of this phenomenon has not been delineated, but is believed to be a result of placental release of vasopressinase.

Nephrogenic Diabetes Insipidus. Failure of the kidney to respond to normal or increased concentrations of AVP can cause NDI. In the majority of these patients, AVP is incapable of stimulating cyclic adenosine monophosphate (cAMP) formation. Two causes have been described for this disorder: (1) mutation in the vasopressin receptor and (2) mutations in the aquaporin-2 water channels. The vasopressin receptor mutation form of NDI is an X-chromosome–linked disorder that mostly affects males. Females are more likely to have the aquaporin-2 water channel gene defect on chromosome 12,q12-13, which produces an autosomal recessive disease. Acquired forms of NDI may be caused by metabolic disorders (hypokalemia, hypercalcemia, and amyloidosis), drugs (lithium, demeclocycline, and barbiturates), and renal diseases (polycystic disease and chronic renal failure). NDI may also be seen in the absence of these factors (idiopathic).

Psychogenic or Primary Polydipsia. A chronic, excessive intake of water suppresses AVP secretion and produces hypotonic polyuria. The polyuria and polydipsia are usually not as sustained as in HDI or NDI; nocturnal polyuria also is less frequent. Psychogenic factors are most commonly associated with this disorder, but hypothalamic disease affecting the thirst center may be a cause. Drugs also can affect the thirst center and result in primary polydipsia.

BOX 50-8 Diagnosis of Diabetes Insipidus

1. Document polyuria (urine volume >2.5 L/day) and exclude glycosuria. If desired, creatinine excretion can be measured as an estimate of completeness of urine collections; substances that influence ADH secretion should be avoided (e.g., nicotine, alcohol, and caffeine). If plasma osmolality is ≥295 mOsm/kg or if serum sodium concentration ≥145 mmol/L, primary polydipsia is unlikely; proceed with the overnight water deprivation test (Box 50-9) or the hypertonic saline infusion test (Box 50-10).
2. Overnight water deprivation test (Box 50-9): If the ratio of urine to plasma osmolality is <1.5 at the end of the test, primary polydipsia is unlikely. Measure plasma and urine osmolalities and plasma ADH concentrations at the end of the test; use these relationships to differentiate normal, nephrogenic, or hypothalamic diabetes insipidus, and psychogenic polydipsia. If urine osmolality is ≤400 mOsm/kg at the end of the test, give 5 U of aqueous vasopressin subcutaneously. If urine osmolality increases ≥10%, hypothalamic diabetes insipidus is probable; if urine osmolality does not increase, nephrogenic diabetes insipidus is highly probable.
3. Hypertonic saline infusion test (Box 50-10): Plot plasma osmolality versus plasma ADH concentration.

ADH, Antidiuretic hormone.

BOX 50-9 Protocol for the Overnight Water Deprivation Test

Rationale Dehydration provides a strong stimulus for ADH release, which can be assessed indirectly by measuring urine osmolality or directly by measuring plasma ADH. If urine remains hyposmolal during water deprivation, the administration of ADH helps differentiate HDI from NDI.

Procedure This test can be conducted if the plasma osmolality is <295 mOsm/kg. The patient is weighed at 22:00 at which time plasma and urine specimens are collected for the determination of sodium and osmolality. No oral intake is allowed until the test is terminated. Care is taken to ensure that the patient's body weight does not decrease by more than 5% during the test. Beginning at 6:00, the patient is weighed again. Urine is collected hourly for measurement of volume and determination of osmolality. When urine osmolality is stable (a change of ≤30 mOsm/kg for 2 consecutive hours, which usually takes 8 to 12 hours to occur), specimens are collected for plasma osmolality (and plasma ADH, if desired). Five units of aqueous vasopressin (ADH) are given subcutaneously, and urine osmolality is measured 1 hour later. The test is then terminated.

Interpretation Normal individuals will lose 3% or less of body weight, will not develop an elevated serum sodium or plasma osmolality, and will produce a concentrated urine (osmolality ≤400 mOsm/kg) with no further increase in urine osmolality after ADH administration. Patients with HDI show an increase in plasma osmolality and serum sodium; their urine will be less concentrated than normal (≤400 mOsm/kg, but often less than plasma) and plasma ADH concentrations will not rise normally; and urine osmolality will increase by 10% or greater after ADH administration. Patients with NDI show plasma and urine osmolalities that are similar to those of patients with HDI during water dehydration; however, they show high ADH concentrations as the plasma osmolality exceeds 300 mOsm/kg. Also, they will not show a significant increase in urine osmolality after ADH injection. In patients with psychogenic polydipsia, normal responses may be seen; however, the period of water deprivation may need to be prolonged. Measuring plasma ADH in response to hypertonic saline (see Box 50-11) may be needed if the diagnosis remains unclear.

ADH, Antidiuretic hormone; *HDI,* hypothalamic diabetes insipidus; *NDI,* nephrogenic diabetes insipidus.

Diagnostic Studies. A differential diagnosis of polyuric states can be made using measurements of plasma and urine osmolality and plasma AVP concentrations; a recommended strategy is shown in Box 50-8.

The classic approach to the diagnosis of polyuric disorders is the *overnight water deprivation test* usually conducted in a hospital setting because of immediate concerns of profound hypotension and possible death (Box 50-9).[87,102] If access to water is denied, patients with HDI or NDI cannot conserve free water and thus show weight loss, hypernatremia, and an increase in plasma osmolality; urine osmolality remains low and is often less than that of plasma. Once urine osmolality is stabilized, aqueous vasopressin is given subcutaneously, and urine osmolality is measured 60 minutes later. An increase in urine osmolality of >10% suggests HDI, whereas failure to increase urine osmolality after vasopressin injection supports the diagnosis of NDI. Most patients with psychogenic polydipsia usually have a normal urine osmolality after water deprivation, but some of these patients can fail to produce concentrated urine unless water deprivation is prolonged. When psychogenic polydipsia is suspected, the patient should be given a minimum of 1 L of normal saline IV to reestablish the renal medullary concentrating gradient so that the patient can respond appropriately to AVP.

Measurements of AVP in plasma or urine can also be used to establish the correct diagnosis in difficult cases (Figure 50-13). After water deprivation, patients with HDI have low or inappropriately normal plasma vasopressin concentrations relative to a high plasma osmolality or low urine osmolality; patients with NDI have high plasma concentrations of vasopressin when plasma osmolality exceeds 300 mOsm/kg and low urine osmolality; and patients with primary polydipsia have normal concentrations of vasopressin relative to their plasma osmolality.[12] Because AVP concentrations discriminate best when plasma osmolality is high, vasopressin can also be measured after hypertonic saline is administered to the patient (Box 50-10); this saline infusion test is usually not needed unless results of the water deprivation test are inconclusive.

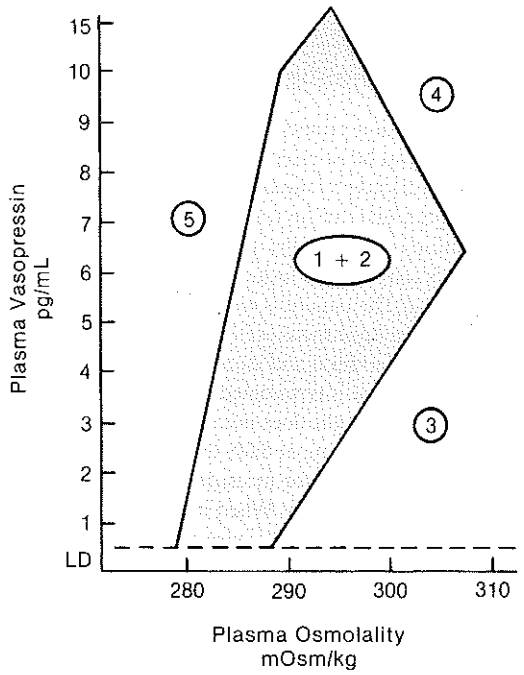

Figure 50-13 Retention of plasma vasopressin to osmolality. *Regions 1 and 2* represent the normal reference interval and values seen in subjects with psychogenic polydipsia. *Region 3* indicates central diabetes insipidus, *Region 4* is NDI, and *Region 5* is SIADH. LD denotes the lowest detectable plasma vasopressin correlation with this assay. *(Modified and abstracted from Zerbe RL, Robertson GL. A comparison of plasma vasopressin measurements with a standard indirect test in the differential diagnosis of polyuria. N Engl J Med 1981;305:1539-46.)*

Syndrome of Inappropriate Antidiuretic Hormone Secretion (SIADH)

The autonomous, sustained production of AVP in the absence of known stimuli for its release is called SIADH. In this syndrome, plasma AVP concentrations are "inappropriately" increased relative to a low plasma osmolality and to a normal or increased plasma volume. SIADH may be the result of one of several factors: production of vasopressin by a malignancy (such as a small cell carcinoma of the lung), the presence of acute and chronic diseases of the central nervous system, pulmonary disorders, or a side effect of certain drug therapies. In addition, as many as 10% of patients undergoing pituitary surgery have a transient SIADH approximately 8 to 9 days after surgery (when the patient is at home), which responds to water restriction (2 to 3 days) and resolves without recurrence. In SIADH, a primary excess of AVP, coupled with unrestricted fluid intake, promotes increased reabsorption of free water by the kidney. The result is a decreased urine volume and an increased urine sodium concentration and urine osmolality. As a consequence of water retention, these patients become modestly volume expanded. The increase in intravascular volume causes hemodilution accompanied by dilutional hyponatremia and a low plasma osmolality. Volume expansion also decreases renal sodium reabsorption and thus further increases the urine sodium concentration.

BOX 50-10 Protocol for the Saline Infusion Test for Diabetes Insipidus

Rationale An increase in plasma osmolality is a strong stimulus for release of ADH. The administration of hypertonic saline intravenously will produce a hyperosmolal state, causing a rise in plasma ADH concentration. Plasma ADH concentration can be plotted against plasma osmolality and compared with a nomogram.

Procedure An intravenous infusion of 3% saline is begun at a minimum rate to maintain flow; two baseline blood specimens are drawn 15 minutes apart for plasma osmolality and ADH determination. The rate of saline infusion is then adjusted to 0.1 mL/kg/min and maintained with an infusion pump for 2 hours. Blood specimens are collected for plasma osmolality and ADH measurement every 15 minutes during this 2-hour period.

Interpretation Normal subjects show a plasma ADH that is >7 pg/mL when plasma osmolality is ≥310 mOsm/kg.

ADH, Antidiuretic hormone.

The most common cause of hyponatremia in hospital patients is SIADH.[2] However, other disorders can cause dilutional hyponatremia and must be differentiated from SIADH. These conditions include (1) congestive heart failure, (2) renal insufficiency, (3) nephrotic syndrome, (4) liver cirrhosis, and (5) hypothyroidism. Excessive administration of hypotonic fluids and treatment with drugs that stimulate AVP (e.g., chlorpropamide, vincristine, clofibrate, carbamazepine, nicotine, phenothiazines, and cyclophosphamide) can cause dilutional hyponatremia as well. Hyponatremia may also occur from renal or extrarenal sodium losses (depletional hyponatremia) as a result of vomiting, diarrhea, excessive sweating, diuretic abuse, salt-losing nephropathy, or mineralocorticoid deficiency.

The clinical manifestations of hyponatremia are nonspecific; weakness and apathy occur in mild cases, and central nervous system changes (lethargy, coma, and seizures) are present in more severe cases. No signs or symptoms are specific for SIADH. History, physical examination, and routine laboratory test results often suggest that hyponatremia is dilutional or depletional.

Measurements of sodium and osmolality in blood and urine, combined with a clinical assessment of volume status, usually permit the appropriate differential diagnosis of hyponatremic conditions (Box 50-11). The typical patient with SIADH has a hyposmolar plasma (<270 mOsm/kg), a urine osmolality that is slightly greater than that of plasma, and a urine sodium concentration that is inappropriately elevated (~40 to 80 mmol/L). Patients with dilutional hyponatremia resulting from excess water intake have a hypotonic plasma, an unremarkable urine sodium concentration (<20 mmol/L), and a dilute urine (a urine osmolality that is less than that of plasma). Patients with depletional

BOX 50-11 Diagnosis of Syndrome of Inappropriate Antidiuretic Hormone (SIADH)

Document plasma hypoosmolality (≤275 mOsm/kg) and hyponatremia (sodium concentration of ≤130 mmol/L). Use history, physical examination, and appropriate laboratory tests to exclude cardiac, hepatic, renal, thyroid, or adrenal failure; and the effects of pituitary surgery, diuretic therapy, or medications known to stimulate ADH release. (SIADH cannot be diagnosed unless these factors are corrected.) Measure the urine sodium concentration and osmolality. Urine osmolality greater than plasma osmolality and without correspondingly low urine sodium concentration (usually >60 mmol/L) indicates that SIADH is probable. If further tests seem to be indicated: (1) Perform water loading test (Box 50-12). Use with caution. Normal results exclude SIADH. (2) Measure plasma ADH and plasma renin concentrations. SIADH is characterized by high ADH concentration and low renin concentration. If plasma ADH and renin concentrations are both low, a primary defect in renal water excretion is present.

ADH, Antidiuretic hormone; *SIADH,* syndrome of inappropriate antidiuretic hormone.

BOX 50-12 Protocol for the Water Loading Test for Syndrome of Inappropriate Antidiuretic Hormone (SIADH)

Rationale An excess of ADH leads to hyponatremia, because it interferes with the ability of the kidneys to excrete a water load normally. This test is useful if SIADH is suspected in a patient with normal or near-normal serum sodium and plasma osmolality or in a patient with "reset osmostat." This test should not be performed in patients who are already significantly hyponatremic because of the danger that the water load will worsen the hyponatremia.

Procedure The test is started in the morning 2 hours after the patient has eaten a light breakfast. Plasma and urine osmolalities are measured. The patient is given water to drink (20 mL/kg) over a 15- to 30-minute period; lightly salted crackers may be given with the water if needed. The patient is kept in a recumbent position, and specimens are taken hourly for the next 4 hours for assessment of plasma and urine osmolality. Total urine output is measured.

Interpretation Plasma osmolality should decrease by ≥5 mOsm/kg, and urine osmolality should drop to ≤100 mOsm/kg, with 90% or more of the water load excreted in 4 hours. SIADH is characterized by excretion of <90% of the water load and by urine osmolality that remains at >100 mOsm/kg. Plasma ADH may be measured at 90 or 120 minutes after the water loading to confirm the diagnosis. Subnormal responses are seen with glucocorticoid deficiency, hypothyroidism, and renal diseases.

ADH, Antidiuretic hormone; *SIADH,* syndrome of inappropriate antidiuretic hormone.

hyponatremia caused by extrarenal sodium loss have hypotonic plasma, a low urine sodium concentration (usually <20 mmol/L), and a urine osmolality that is greater than that of plasma; patients with depletional hyponatremia caused by impaired renal conservation of sodium have similar results except that their urine sodium concentrations are elevated.

If the cause for mild hyponatremia remains unclear after the above tests are performed, a water-loading test may be performed (Box 50-12). This test is potentially dangerous in patients with severe hyponatremia and should not be performed if the serum sodium concentration is <130 mmol/L. Patients with SIADH have impaired excretion of the water load and fail to dilute their urine. Measurements of vasopressin in plasma are not usually needed to make a diagnosis of SIADH, but basal values would be expected to be inappropriately high relative to plasma hyposmolality. Interpretations of plasma vasopressin concentrations are sometimes complicated, because values are often within the physiological reference interval or are undetectable.[93]

Measurement of Arginine Vasopressin

Numerous immunoassays for measuring AVP in plasma or urine have been described.[58] However, their routine clinical application has been hampered because of method complexity and lack of assay sensitivity and specificity. With most plasma assays, a preliminary extraction procedure is required, not only to concentrate the minute amount of hormone that is present in the specimen, but also to remove nonspecific interfering substances.

Procedures for extracting and concentrating AVP from biological fluids often involve the use of solvents such as acetone, petroleum ether, or ethanol.[23] Alternatively, column chromatography using octadecyl silica (C_{18}) columns is an efficient purification technique.[7,132,137] Although a few nonisotopic immunoassays have been developed for ADH,[52,128] most clinical laboratories use some variant of an RIA; complete test kits or individual components (antivasopressin antisera and vasopressin labeled with ^{125}I) are available commercially. Most RIAs are of the delayed-addition type; this nonequilibrium approach provides better sensitivity than equilibrium assays at low hormone concentrations. Separation of bound and free ligand is commonly achieved using second-antibody precipitation techniques.

In the method described by Crawford and Gyory,[29] plasma samples (0.5 mL) are acidified, extracted through C18 Sep-Pak cartridges, and evaporated to dryness. The concentrated specimen is then reconstituted with buffer and incubated with rabbit antivasopressin antisera for 26 to 30 hours at 5 °C. During this time, essentially all the endogenous vasopressin binds to the antibody. Radioactive ^{125}I-labeled vasopressin is subsequently added, and the mixture is incubated for an additional 16 hours at 5 °C. An antirabbit antibody-coated cellulose suspension is used to precipitate the antibody-bound hormone immunologically. The detection limit of this method is 0.1 pg per tube (0.45 ng/L or 0.42 pmol/L). The between-run CV is 7.6% to

11.3% at concentrations ranging from 3 to 10 ng/L (2.8 to 9.3 pmol/L).

Specimen Collection and Storage

Blood specimens for AVP are collected into prechilled tubes containing EDTA as an anticoagulant. Most procedures recommend that specimens be delivered to the laboratory on ice and centrifuged at 4 °C within 30 minutes of collection. The plasma is then removed and stored or shipped frozen at −20 °C until analysis is performed. Random urine specimens are collected without preservatives; alternatively, complete 24-hour urine specimens may be collected in 10 mL of 6 mol/L hydrochloric acid.[95] Significant deterioration of both hormones occurs with prolonged storage.

Reference Intervals

The plasma concentration of AVP in healthy adults (ages 24 to 42 years) with normal water intake and normal physical activity is 0.35 to 11.94 ng/L (0.32 to 11.80 pmol/L).[52] For best interpretation of results, plasma AVP values should be correlated with serum or plasma osmolality[125]:

AVP		
ng/L	**pmol/L**	**Osmolality mOsm/kg**
<1.5	<1.4	270-280
<2.5	<2.3	280-285
1-5	0.9-4.6	285-290
2-7	1.9-6.5	290-295
4-12	3.7-11.1	295-300

The reference interval for AVP in a random urine specimen is reported to be 1 to 112 pg/mL.[90]

Oxytocin

Oxytocin is a nonapeptide secreted by the magnicellular neurons of the hypothalamus and stored in the neurohypophysis along with AVP. It promotes uterine contractions and milk ejection and contributes to the second stage of labor.

Regulation of Secretion

The primary stimulus for oxytocin release is suckling. Stimulation of tactile receptors located around the nipples of the breasts initiates an action potential that propagates along afferent nerve fibers through the spinal cord and midbrain to the hypothalamus. The cell bodies in the paraventricular nucleus are then stimulated, resulting in the episodic release of oxytocin. Stretch receptors in the uterus and possibly in the vaginal mucosa may also initiate action potentials in afferent nerve fibers that ultimately stimulate the release of oxytocin from the neurohypophysis. Estrogens enhance the response of oxytocin to these stimuli. The influence of other parts of the brain on the release of oxytocin has been reported; emotional stress, for instance, inhibits lactation.

Physiological Actions

Oxytocin is present in males and females, but its physiological effects are known only for females. Oxytocin stimulates contraction of the uterine myometrium only in the estrogen-primed uterus and can activate the smooth muscles associated with milk letdown with nursing. Thus the effects of oxytocin appear limited to events of parturition and lactation. Oxytocin has been used as a therapeutic agent to induce labor, but the physiological mechanism whereby it induces uterine contractions remains obscure. There is some evidence to show that oxytocin can stimulate prostaglandin production, which may be the vehicle through which myometrial contractility is enhanced. There is evidence indicating that oxytocin may affect the central nervous system and thus modulate human behavior.[84] Progestins are believed to counteract the actions of oxytocin.

Measurement of Oxytocin

Numerous immunoassays for measuring oxytocin in plasma or urine have been described.[58] However, their routine clinical application has been limited because of a lack of physiological relevance to human reproductive disorders and because of a lack of easy-to-use immunoassays with acceptable sensitivity and specificity. With most plasma assays, a preliminary extraction procedure with column chromatography is required, not only to concentrate the minute amount of hormone that is present in the specimen, but also to remove nonspecific interfering substances.

Specimen Collection and Storage

Blood specimens for oxytocin are collected into prechilled tubes containing EDTA as an anticoagulant. Most procedures recommend that specimens be delivered to the laboratory on ice and centrifuged at 4 °C within 30 minutes of collection. The plasma is then removed and stored frozen at −20 °C until analysis is performed. Random urine specimens are collected without preservatives; alternatively, complete 24-hour urine specimens may be collected in 10 mL of 6 mol/L hydrochloric acid.[95] Significant deterioration of both hormones occurs with prolonged storage.

Reference Intervals

Oxytocin values are quantified relative to the bioassay potency of a synthetic reference preparation. Plasma results are reported as microunits per milliliter (1 μU is equivalent to 2 pg of synthetic oxytocin):

	Oxytocin μU/mL[73]
Males	1.1-1.9
Females	
Nonpregnant	1.0-1.8
Second stage of labor	3.1-5.3

CHAPTER 51

The Adrenal Cortex*

Laurence M. Demers, Ph.D., F.A.C.B., D.A.B.C.C.

An adrenal gland lies at the upper pole of each human kidney. Each gland is pyramidal in shape, is approximately 2 to 3 cm in width, 4 to 6 cm long, 1 cm thick, and weighs approximately 4 g, regardless of age, weight, or gender.[135] Each gland consists of a yellow, outer cortex and a gray, inner medulla. Beneath the capsule of the outer cortex lies the zona glomerulosa that constitutes approximately 15% of the cortex. The next layer is the zona fasciculata that comprises about 75% of the cortex with large and lipid-laden cells. The innermost zone is the zona reticularis that contains irregular looking cells with little lipid content. The cells of the adrenal cortex synthesize steroid hormones, which are discussed in this chapter, and the cells of the adrenal medulla synthesize catecholamines, such as dopamine, norepinephrine, and epinephrine aromatic amines, which have important consequences for blood pressure regulation. The catecholamines and their function are discussed in Chapter 29.

The human adrenal cortex secretes three major classes of *steroid* hormones that possess a wide range of physiological functions. These include the glucocorticoids, the mineralocorticoids, and the adrenal androgens. This chapter begins with a section on general steroid biochemistry, followed by a discussion of the clinical and biological functions of the steroid hormones produced by the adrenal cortex.

GENERAL STEROID CHEMISTRY

Chemical Structure

Steroids are hormones that contain the cyclopentanoperhydrophenanthrene nucleus as the backbone structure (Figure 51-1). The three six-sided rings (A, B, and C) constitute the phenanthrene nucleus, to which is attached the (D) or cyclopentane ring. The prefix "perhydro" refers to the saturation of the compound with hydrogen atoms. This class of compounds includes such natural products as sterols (e.g., cholesterol), bile acids (e.g., cholanic acid), sex hormones (e.g., estrogens and androgens), vitamin D, and the corticosteroids. The steroid hormones contain up to 21 carbon atoms (C_{21} steroids), numbered as shown in Figure 51-1. The carbon atoms composing the rings and the hydrogen atoms attached to them are not usually written into the structure unless it is necessary to draw special attention to configuration. Furthermore, in all naturally occurring steroid hormones, the projected solid line from the carbon atom at position 10 or 13 usually designates the presence of an angular (CH_3) group, unless otherwise indicated.

Steroids are three-dimensional molecules with their constituent atoms lying in different planes—such spatial arrangements give rise to *isomers.* The direction of the hydrogen atoms, of the substituents, and of the side chain plays a much more important role in the distinction of various isomers of the steroid compounds than does the relative position of the carbon atoms in the rings. Thus the isomers resulting from fusion of two rings are decided on the basis of the spatial relationship between the hydrogen atoms or the substituents at common carbon atoms. When rings A and B are fused, two isomers are possible, depending on whether the hydrogen atom at C-5 and the methyl group at C-10 are on the same or the opposite side of the plane of the rings. If the hydrogen atom points in the same direction as that of the angular methyl group at C-10, the compound is said to be in the *cis* or *normal* form. If, however, they are on the opposite sides, the compound is said to be in the *trans* or *allo* form. Although rings A and B may be either *cis* or *trans,* the rings B-C and C-D have the *trans* configuration in all naturally occurring steroid hormones.

The two methyl groups attached to C-10 and C-13 lie above the plane of the molecule and are customarily the points of reference for describing the spatial orientation of

Hydrogen atom and methyl group are on the same side (above the plane of the paper: 5β-isomer.)

trans-

Hydrogen atom is on the opposite side (below the plane of the paper: 5α-isomer.)

Figure 51-2 Fusion of rings A and B and their isomerism in naturally occurring steroids.

other substituents in the steroid nucleus. Depending on which side of the molecule that substituents are attached relative to these two methyl groups, they are said to have either an α- or β-orientation (Figure 51-2). For example, when substituents are on the same side as the two methyl groups, they are said to possess a β-*configuration,* which is indicated by a solid line (—) joining the substituents to the appropriate carbon atoms in the nucleus. Substituents on the opposite side are attached by a broken line (— — —) to denote an α-*configuration.* In the structures shown in Figure 51-2, when the hydrogen substituent at C-5 is *cis,* the isomer is the 5β-isomer, and when it is *trans,* the isomer is accordingly the 5α-isomer. Similarly the substituents at C-3, C-11, C-17, or any other carbon atoms are indicated as either α- or β-configuration, depending on their spatial orientation relative to these methyl groups (C-10 and C-13).

The different steroids containing the cyclopentanoperhydrophenanthrene nucleus differ from one another by the introduction of double bonds between certain pairs of carbon atoms, by the introduction of substituents for the hydrogen atoms, or by the addition or deletion of a specific type of side chain. On the basis of such structural characteristics, the steroidal compounds are classified as derivatives of certain parent hydrocarbons, namely, *estrane* (for estrogens), *androstane* (for androgens), and *pregnane* (for corticosteroids and progestins). Chemically, estranes are C_{18} compounds that lack one methyl group at C-10, androstanes are C_{19} compounds that possess 5α- or 5β-configuration, and pregnanes are C_{21} compounds that have a β-oriented, ethyl side chain (—CH_2—CH_3) attached to C-17. Further discussion of the chemistry of estranes and androstanes is presented in more detail in Chapter 53.

The prefix *allo-* is a term used to describe the stereoisomerism of the hydrogen atom at C-5. When the configuration differs at any other carbon atom, the prefix *epi-* is used (e.g., androsterone possesses a 3α-hydroxyl group, and epiandrosterone a 3β-hydroxyl group; testosterone possesses a 17β-hydroxyl group, and epitestosterone a 17α-hydroxyl group).

To describe a compound with chemical nomenclature, a variety of other suffixes and prefixes are used. The suffix *-ane* indicates a fully saturated compound (e.g., pregn*ane*); *-ene,* the presence of one double bond (e.g., pregn*ene*); *-diene,* two double bonds; and *-triene,* three double bonds; the terminal "e" is omitted before a vowel (e.g., -4-en-β3-ol). The position of the double bond is indicated by the number of the carbon atom from which it originates, and it is understood to terminate at the next higher carbon atom (e.g., "4-ene" means that a double bond lies between C-4 and C-5). However, when an alternative is possible, as in a double bond originating at C-8 in the estrane nucleus that can terminate at C-9 or C-14, the number of the carbon atom at which the bond ends is written in parentheses. Thus a double bond at C-8 terminating at C-14 is designated as "8(14)-ene." A formerly used prefix for a double bond is the symbol Δ, with a superscript indicating the position of the double bond (e.g., Δ^5). An alcohol (—OH substituent of the nucleus) is indicated by the suffix *-ol* (two alcohol groups as *-diol,* three as *-triol,* etc.), or by the prefix *hydroxy-* or *oxy-* (*dihydroxy-* for two, *trihydroxy-* for three, etc.). Ketones (=CO) are identified by the suffixes *-one* for one keto group, *-dione* for two keto groups, and so on, or by the prefix *oxo-* (Table 51-1).

In naming a compound containing double bonds, hydroxyl groups, and ketones, priorities are given to the use of suffixes and prefixes. Thus hydroxyl groups are indicated by the prefix followed by the suffixes for other substituents. Accordingly the systematic name of dehydroepiandrosterone is written as 3β-hydroxy-androst-5-en-17-one. Note that to denote the bond of unsaturation, the first part of the parent hydrocarbon is followed by the position of the bond and the suffix (e.g., androst-5-en). If the prefix Δ for unsaturation is chosen, then suffixes for both the hydroxyl and the ketone groups are used (e.g., Δ^5-androsten-3β-ol-17-one). When only one kind of substituent is present, the use of a suffix is customary (e.g., pregnanediol [5β-pregnane-3α, 20α-diol] and androstenedione [androst-4-ene-3,17-dione]).

The utility of the *systematic name* of a compound lies in the information that it provides about the parent compound, the position of bond unsaturation, and the nature, position, and orientation of substituents. The *trivial name,* as the term suggests, conveys little or no information about the chemical origin and characteristics of a compound (e.g., cortisol, progesterone, and testosterone). The trivial and systematic names of some of the important steroid hormones are given in Table 51-2.

TABLE 51-1 Common Suffixes and Prefixes for Steroids

Suffix or Prefix	Definition
Suffix	
-al	Aldehyde group
-ane	Saturated hydrocarbon
-ene	Unsaturated hydrocarbon
-ol	Hydroxyl group
-one	Ketone group
Prefix	
hydroxy- (oxy-)	Hydroxyl group
keto- (oxo-)	Ketone
deoxy- (desoxy-)	Replacement of hydroxyl group by hydrogen
dehydro-	Loss of two hydrogen atoms from adjacent carbon atoms
dihydro-	Addition of two hydrogen atoms
cis-	Spatial arrangement of two substituents on the same side of the molecule
trans-	Spatial arrangement of two substituents on opposite sides of the molecule
α-	Substituent that is *trans* to the methyl group at C-10
β-	Substituent that is *cis* to the methyl group at C-10
epi-	Isomeric in configuration at any carbon atom except at the junction of two rings
Δn-	Position of unsaturated bond

TABLE 51-2 Trivial and Systematic Names of Some Important Steroid Hormones

Trivial Name	Systematic Name
Aldosterone	11β-21-Dihydroxy-3,20-dioxopregn-4-en-18-al
Androstenedione	Androst-4-ene-3,11,17-trione
Androsterone	3α-Hydroxy-5α-androstan-17-one
Cortisol	11β,17,21-Trihydroxypregn-4-ene-3,20-dione
Dehydroepiandrosterone	3β-Hydroxyandrost-5-en-17-one
Estradiol-17β	Estra-1,3,5(10)-triene-3,17β-diol
Estriol	Estra-1,3,5(10)-triene-3,16α,17β-triol
Estrone	3-Hydroxyestra-1,3,5(10)-trien-17-one
Etiocholanolone	3α-Hydroxy-5β-androstan-17-one
Pregnanediol	5β-Pregnane-3α,20α-diol
Progesterone	Pregn-4-ene-3,20-dione
Testosterone	17β-Hydroxy-androst-4-en-3-one
Urocortisol (tetrahydro F)	3α,11β,17,21-Tetrahydroxy-5β-pregnan-20-one

In addition to the usual suffixes and prefixes just discussed, a few special prefixes are usually used for the semitrivial names of the compounds. Thus the prefix *dehydro-* is used to indicate the loss of two hydrogen atoms from adjacent carbon atoms with the formation of a double bond (e.g., dehydroepiandrosterone). The prefix *dihydro-* or *tetrahydro-* indicates the addition of two or four hydrogen atoms to the molecule, respectively, as in dihydrocortisol and tetrahydrocortisol. The replacement of a hydroxyl group by hydrogen (COH CH) is denoted by the prefix *deoxy-* (or *desoxy-* [e.g., 11-deoxycorticosterone]).

Steroid nomenclature is officially defined by the International Union of Pure and Applied Chemistry (IUPAC).

BIOCHEMISTRY

Human steroid hormones are synthesized primarily from cholesterol in the adrenal glands and gonads. In most cases, cholesterol is made available from the circulation in the form of low-density lipoprotein cholesterol (LDL). The uptake of LDL takes place by way of specific cell surface LDL receptors on the adrenal gland surface that internalize the cholesterol moiety, releasing it as substrate for steroidogenesis; however, all steroidogenic cells are capable of de novo synthesis from acetyl coenzyme A.[43] To ensure a continuous supply of free cholesterol for steroid synthesis, lipoprotein cholesterol uptake is coordinated with intracellular cholesterol synthesis and with the mobilization of intracellular cholesteryl ester pools. When the rate of cholesterol uptake exceeds the rate of steroidogenesis, intracellular cholesterol synthesis is suppressed, and cholesterol in excess of cellular needs is esterified and stored for future use.

The initial rate limiting step in the transport of intracellular cholesterol to sites of steroidogenesis is mediated by a steroidogenic acute regulatory protein (StAR) that is regulated by adrenocorticotropic hormone (ACTH).

The nature and quantity of steroid hormones produced by the adrenal glands and gonads are different. The difference is inherent in the degree of activity of certain enzyme systems. For example, the enzymes 11β-hydroxylase and 21-hydroxylase, present only in the adrenal glands, synthesize steroids characteristic of the adrenal glands. Similarly the ovaries and the testes contain enzymes that synthesize the male and female sex hormones (see Chapter 53).

TABLE 51-3 The Genes, Chromosomal Location, and Common Names of the Adrenal Steroidogenic Enzymes

Enzyme Name	Gene	Chromosome Location
11-Aldosterone synthase	CYP11B2	8q24.3
Cholesterol side-chain cleavage (SCC, desmolase)	CYP11A1	15q23-q24
17α-Hydroxylase/17,20 lyase	CYP17	10q24.3
21-Hydroxylase	CYP21A2	6p21.3
β-Hydroxylase	CYP11B1	8q24.3
3β-Hydroxysteroid dehydrogenase (3β-HSD)	HSD3B2	1p13.1

Biosynthesis

Enzymes participating in the biosynthesis of steroid hormones are broadly classified as (1) hydroxylases, (2) lyases, (3) dehydrogenases, and (4) isomerases.

Hydroxylases

These enzymes are all cytochrome P-450 enzymes[175] and catalyze the substitution of the hydroxyl group (—OH) for hydrogen (—H). For example, 21-hydroxylase (also known as "P-450$_{C21}$") introduces a hydroxyl group at C-21. Similarly, 11β-hydroxylase (P-450$_{C11}$) introduces a hydroxyl group at the β-position of C-11. The required cofactors are nicotinamide-adenine dinucleotide phosphate (NADP) and molecular oxygen; the reaction is irreversible. The hydroxylation is carried out in conjunction with an electron transport system that consists of NADPH → flavoprotein → nonheme iron protein → cytochrome P-450 → oxygen. Cytochrome P-450 couples with specific hydroxylases for the introduction of an atom of oxygen into the steroid molecule.

Lyases

Enzymes with lyase activity are required for cleavage of the side chain. Previously, it was thought that three distinct enzymes, including a 20,22-lyase, participated in the conversion of cholesterol to pregnenolone. However, it is now known that a single cholesterol side-chain cleavage enzyme (P-450$_{SCC}$) catalyzes the complete reaction.[87] This enzyme is located within mitochondria and participates in an electron shuttle system where the oxidation and hydroxylation of the different adrenal steroids takes place. The C_{21} steroid hormones are transformed to C_{19} steroid hormones by the 17,20-lyase activity of P-450$_{C17}$, a microsomal enzyme that also catalyzes the hydroxylation of C-17.

Dehydrogenases

This group of enzymes catalyzes the transfer of hydrogen within the steroid structure (oxidation and reduction). The reaction is in general reversible. The cofactor is either the oxidized or reduced form of nicotinamide-adenine dinucleotide $(NAD)^+$ or $NADP^+$, depending on the direction of the reaction. Examples include 3β-hydroxysteroid dehydrogenase, 11β-hydroxysteroid dehydrogenase, 17β-hydroxysteroid dehydrogenase, Δ^5-3β-hydroxysteroid dehydrogenase, and 3α-hydroxysteroid dehydrogenase.

Isomerases

Isomerases catalyze the migration of a double bond. The most important enzyme of this group that is involved in steroidogenesis is Δ^5-*ketosteroid isomerase* ($\Delta^{4,5}$isomerase). The concerted action of Δ^5-3β-hydroxysteroid dehydrogenase and Δ^5-ketosteroid isomerase on pregnenolone produces progesterone through the oxidation of the 3β-hydroxyl group and the migration of a double bond from Δ^5 to Δ^4.

Chromosomes and Genes

The chromosomes and genes responsible for the adrenal steroidogenic enzymes have been identified. Table 51-3 depicts the current nomenclature and chromosome localization for the genes that regulate these enzymes.

Metabolism

The liver is the major site of steroid metabolism. The kidney and the gastrointestinal tract, however, also both carry out important metabolic transformation of steroids.

In addition to using acetate and cholesterol, some steroidogenic tissues produce hormones by converting steroid intermediates that originate from other sources. For example, ovarian granulosa cells can convert androgens produced in thecal cells to estrogens. Some target tissues, such as the prostate, can also convert the circulating form of a steroid to a more potent and bioactive form, which then exerts its effects within the cells. For example, the prostate contains a 5α-reductase that converts testosterone to its biologically more potent form, dihydrotestosterone. Another example of this is the conversion of the adrenal androgen precursor, dehydroepiandrosterone (DHEA), to estrone in fat tissue by way of the aromatase enzyme.

Important biochemical steps for neutralizing the potent biological activity of hormones and facilitating their rapid elimination from the systemic circulation include (1) the introduction of an additional hydroxyl group (e.g., estradiol to estriol); (2) dehydrogenation (e.g., testosterone to androstenedione); (3) reduction of a double bond (e.g., cortisol to dihydrocortisol); and (4) conjugation of an essential hydroxyl group or groups with a chemical moiety, such as glucuronic acid (e.g., testosterone to testosterone glucuronide). The conjugation of these hormones and their metabolites with sulfuric or glucuronic acid is, by far, the

most efficient single metabolic process for their excretion in the urine. Almost all steroid metabolites are excreted as water-soluble glucuronides or sulfates.

ADRENOCORTICAL STEROIDS

The human adrenal cortex secretes a number of steroid hormones that are involved with a wide range of metabolic processes from three discrete anatomical zones; the *zona fasciculata,* the *zona reticularis,* and the *zona glomerulosa.*

General Biochemistry

Steroids isolated from the adrenal glands include the *corticosteroids* and adrenal androgens. Their chemical structure and how they are synthesized and transported are discussed in this section.

Chemical Structure

The *corticosteroids* include the *glucocorticoids* and *mineralocorticoids:* they are physiologically and quantitatively the most important group of adrenal steroids.[122] The structural formula of some of the most significant biologically active corticosteroids are shown in Figure 51-3; their trivial and systematic names are listed in Table 51-2. These compounds all possess a Δ^4-3-keto group (unsaturated double bond between C-4 and C-5 and a keto group at C-3); a side-chain hydroxyl substitution at C-17 in the β-position (above the plane of the paper); and, with the exception of 11-deoxycortisol (compound S) and 11-deoxycorticosterone (DOC), an oxygen function (keto or β-hydroxyl) at C-11. Cortisone and hydrocortisone (cortisol) also have a 17α-hydroxyl group (below the plane of the paper). Corticosteroids show maximal structural specificity. Structural alterations, especially the reduction of the Δ^4-3-keto group, render them biologically inactive. The major corticosteroids—cortisol and aldosterone—are secreted by the adrenal glands at the rate of approximately 25 mg/day and 200 μg/day, respectively.[169]

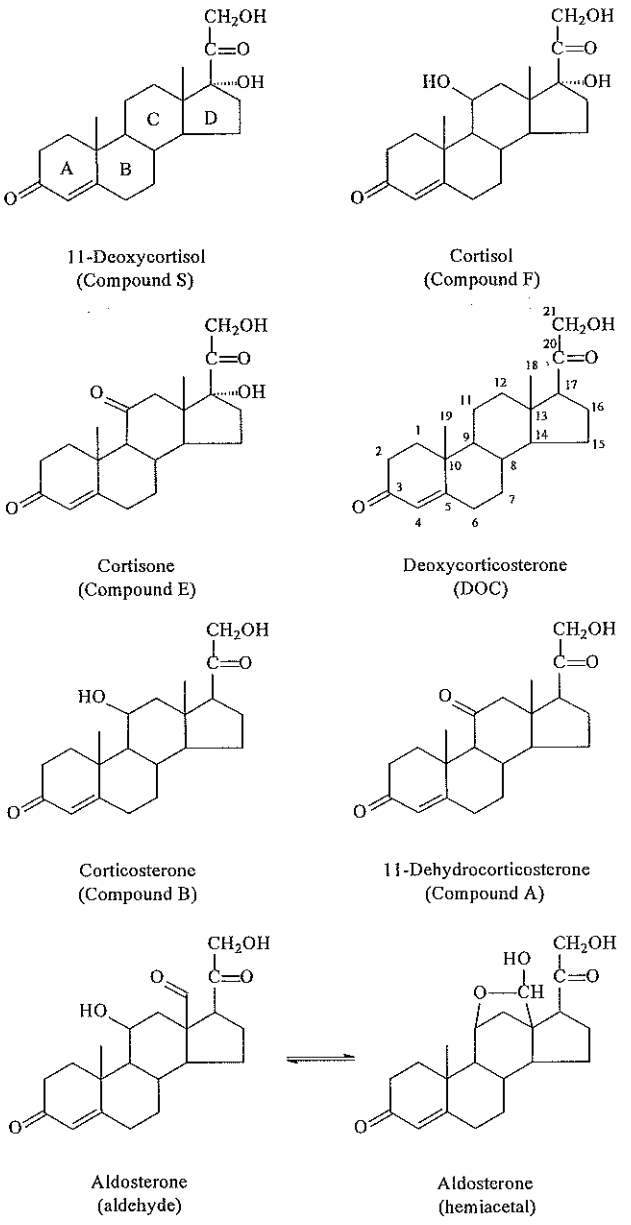

Figure 51-3 Structural formulas and trivial names of some biologically active corticosteroids. Note alphabetical ring system and the numerical system for 21 carbon atoms.

Glucocorticoids

Cortisol is the major glucocorticoid synthesized from cholesterol in the zona fasciculata and reticularis of the human adrenal cortex. Cortisol has major effects on carbohydrate, protein, and lipid metabolism. The influence of *glucocorticoids* on carbohydrate metabolism (Figure 51-4) includes promotion of gluconeogenesis through the activation of key enzymes in this pathway, including phosphoenolpyruvate carboxykinase and glucose-6-phosphatase, increased deposition of liver glycogen through the activation of glycogen synthase and inhibition of glycogen phosphorylase, and a reduction in glucose use and uptake by peripheral tissues, such as muscle and fat. The increase in gluconeogenesis is also due to an increase in muscle protein breakdown and an inhibition of amino acid uptake and protein synthesis in peripheral tissues (muscle, skin, and bone). Glucocorticoids also affect fat metabolism with an activation in lipolysis and the release of free fatty acids into the circulation; when present in excess, glucocorticoids cause a central distribution of fat to the face, neck, and trunk. Glucocorticoids can also stimulate adipocyte differentiation and promote lipogenesis through the activation of enzymes such as lipoprotein lipase and increased messenger ribonucleic acid (mRNA) expression for leptin.

Circulating glucocorticoids have other clinically important effects (see Figure 51-4), such as antiinflammatory effects and a suppression of the immune system. Consequently, glucocorticoids are used therapeutically to treat inflammatory conditions such as rheumatoid arthritis.[169]

Inhibition of the normal immune response results from a gradual destruction of lymphoid tissue, followed by a decline in antibody production and a decrease in the numbers of eosinophils, basophils, and lymphocytes. The reduction in T-lymphocyte counts by glucocorticoids can occur acutely as a result of the redistribution of these cells from the intravascular space to the spleen, lymph nodes, and bone marrow. Thus an increase in the neutrophil count is commonly observed after glucocorticoid administration. The major suppressive effects of glucocorticoids on the inflammatory response and the immune system appear to be through the modulation of cytokine production via an inhibition of nuclear factor kappa B (NF-κB) expression and nuclear translocation. Cytokines released from immunocompetent cells mediate both the acute and chronic phases of inflammation and participate in the control of the immune response (see Chapter 22).

For example, cytokines such as interleukin (IL)-1, IL-2, IL-6, tumor necrosis factor (TNF), interferon-γ, and granulocyte-macrophage colony-stimulating factor (GMCSF) released from white blood cells with activation of the inflammatory response are inhibited by the glucocorticoid's antiinflammatory and immunosuppressive effects (Figure 51-5). Cytokines, such as IL-1, IL-6, and TNF have also been shown to directly stimulate the hypothalamic-pituitary-adrenal (HPA) axis as part of the link that exists between the neuroendocrine system and the immune system. Thus activated immunocompetent cells that produce cytokines suppress the immune response partly through glucocorticoids and the HPA (see Chapter 50). Inhibition of the immune response by exogenous glucocorticoids can sometimes be helpful, as is the case in organ transplant and graft recipients. Suppression of the immune response for any prolonged period of time, however, can render the patient more susceptible to infection.[26]

Glucocorticoids also have antiallergic properties, as a result of and by an inhibition of the synthesis of histamine by mast cells and basophils. Of the naturally occurring corticosteroids, only cortisol and corticosterone possess glucocorticoid activity, with cortisol the most effective. Cortisone and 11-dehydrocorticosterone lack direct glucocorticoid activity, but have potential glucocorticoid activity because they can be metabolized to cortisol and corticosterone, respectively.[135]

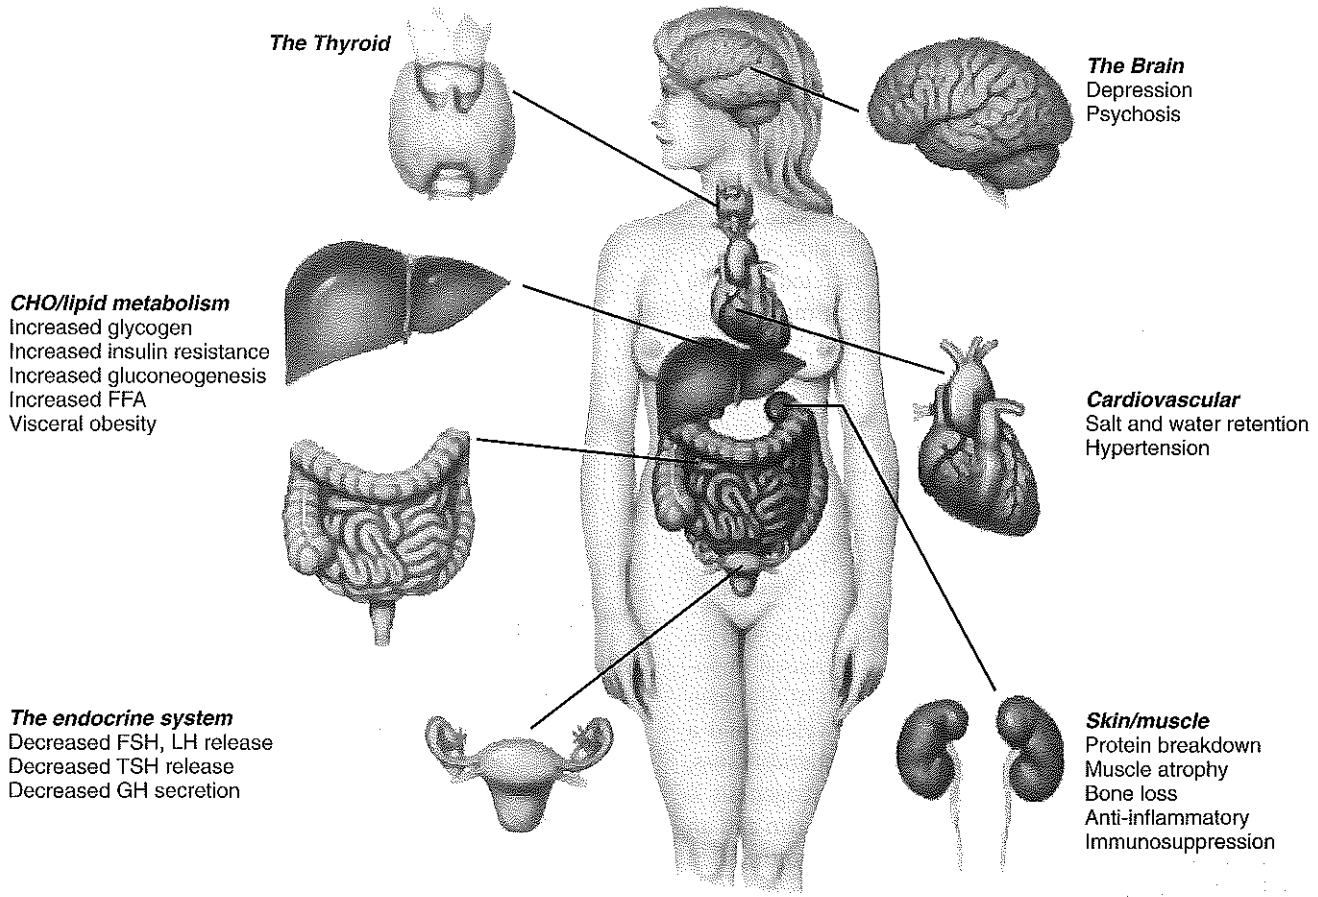

Figure 51-4 Principal effects of glucocorticoids on major organ systems in the human.

Mineralocorticoids

Mineralocorticoid refers to those steroids that regulate salt homeostasis (sodium conservation and potassium loss) and extracellular fluid volume.[6,30,38] Aldosterone is the most potent naturally occurring mineralocorticoid and is synthesized exclusively in the zona glomerulosa region of the adrenal cortex. This zone uniquely contains the enzyme aldosterone synthase, an obligatory enzyme in the synthetic pathway to aldosterone. Other adrenocortical steroids that have mineralocorticoid properties with varying degrees of potency include DOC, 18-hydroxy-DOC, corticosterone, and cortisol. A large number of analogues with mineralocorticoid and glucocorticoid activity have been synthesized; some are actually more potent than those that occur naturally (Table 51-4).

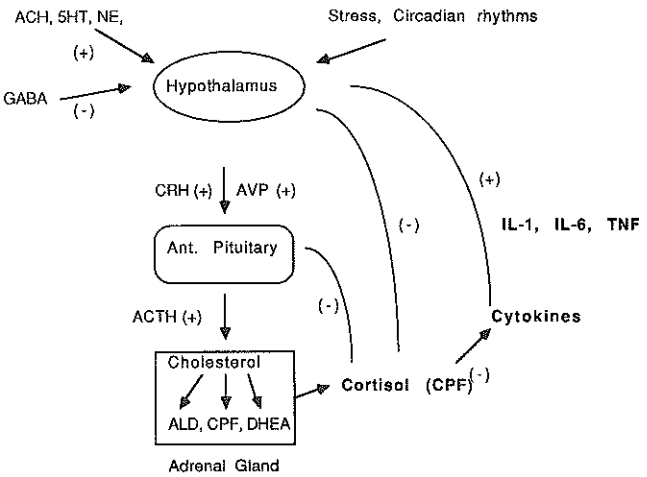

Figure 51-5 Positive and negative factors that affect the HPA axis. Note positive effects of the cytokines on HPA that link an activation of the immune system to the neuroendocrine axis. *ACH,* Acetylcholine; *ACTH,* adrenocorticotropic hormone; *ALD,* aldosterone; *AVP,* arginine vasopressin; *CPF,* cortisol; *CRH,* corticotropin-releasing hormone; *DHEA,* dehydroepiandrosterone; *GABA,* γ-aminobutyric acid; *5HT,* 5-hydroxytryptamine; *IL,* interleukin; *NE,* norepinephrine; *TNF,* tumor necrosis factor.

Adrenal Androgens[140]

In addition to the corticosteroids, the adrenal glands also secrete androgens, progesterone, and estrogen, all of which are produced by the gonads as well. Adrenal androgens are synthesized in the zona fasciculata and/or reticularis from the precursor substrate 17α-hydroxypregnenolone. The adrenal androgens include DHEA, androstenedione, and testosterone (Figure 51-6). DHEA and its sulfated derivative, DHEA sulfate (DHEA-S), are the most important adrenal androgens found in the circulation and are present in the highest concentration. The adult adrenal secretes approximately 6 to 8 mg/day of DHEA, 8 to 16 mg/day of DHEA-S, 1.5 mg/day of androstenedione, and 0.05 mg/day of testosterone. The amount of DHEA and/or DHEA-S produced is second only to that of cortisol among the adrenal steroids released daily into the circulation; these amounts account for about 50% of DHEA and more than 90% of DHEA-S that circulates in plasma. The adrenal glands also produce small amounts of the estrogens estradiol and estrone and insignificant amounts of progesterone and other precursor steroids on a daily basis.[154,189]

Steroidogenesis[169]

Cortisol Biosynthesis

Cortisol is synthesized from pregnenolone by two pathways in the fasciculata and reticularis zones of the adrenal gland. For simplicity, only one pathway is shown in Figure 51-6. The enzyme 17α-hydroxylase and the enzyme complex Δ^5-3β-hydroxysteroid dehydrogenase: Δ^5-ketosteroid isomerase located in the endoplasmic reticulum will synthesize 17α-hydroxyprogesterone from either 17α-hydroxypregnenolone or progesterone. Hydroxylation of this compound by the

TABLE 51-4 Relative Potencies of Corticosteroids

Corticosteroid	Glucocorticoid Activity	Mineralocorticoid Activity
Aldosterone	0.1	400

*Synthetic.

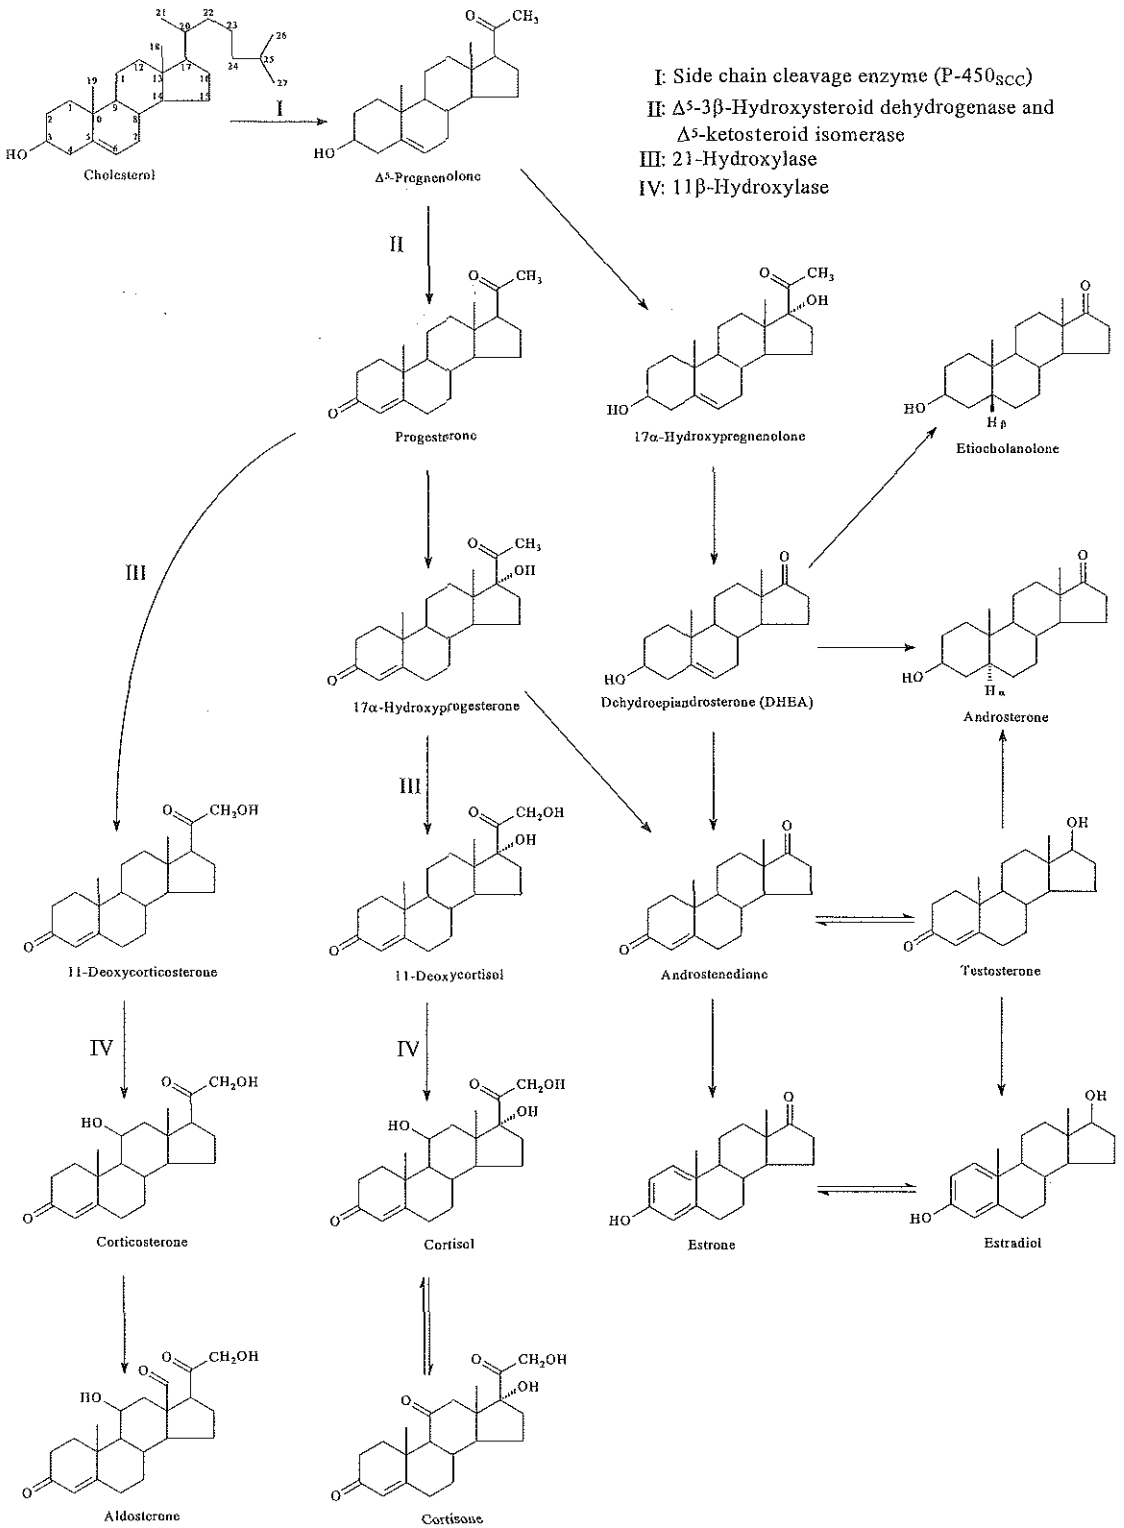

Figure 51-6 Biosynthesis of corticosteroids. Roman numerals I (side-chain cleavage enzyme), II (3-β-ol dehydrogenase and/or Δ^4 isomerase), III (21-hydroxylase), and IV (11β-hydroxylase) indicate sites of major blocks that cause adrenogenital syndromes. *(Copyright 1959 CIBA Pharmaceutical Co. Division of CIBA-GEIGY Corp. Reproduced, with permission, from* The CIBA Collection of Medical Illustrations *by Netter FH. All rights reserved.)*

21-hydroxylase enzyme at the 21α-position forms 11-deoxycortisol, which is then converted to cortisol by an 11β-hydroxylase enzyme located in the mitochondria.[135]

Synthesis of Mineralocorticoids

Aldosterone is the principal mineralocorticoid and is uniquely synthesized in the zona glomerulosa region of the adrenal cortex (see Figure 51-6). This layer lacks the 11β-hydroxylase enzyme required for cortisol synthesis, but it uniquely contains aldosterone synthase, the enzyme complex that catalyzes the formation of aldosterone from corticosterone. Although ACTH stimulates aldosterone production in the zona glomerulosa from progesterone and corticosterone,[169] the major control mechanism for the transformation of corticosterone to aldosterone in this region of the adrenal cortex is the renin-angiotensin system. Renin is an enzyme sensitive to the concentration of sodium in the plasma water perfusing the kidney that is released into the circulation when the sodium concentration in the perfusate declines. A decrease in perfusion pressure to the juxtaglomerular apparatus in the kidney and a negative sodium balance are the primary stimuli for renin release.

Other important regulatory factors that modulate aldosterone biosynthesis either directly or indirectly by affecting the renin-angiotensin system include the adrenergic and dopaminergic systems and the circulating concentrations of sodium and potassium. The renin-angiotensin system is affected by alterations in the adrenergic system by increasing epinephrine release and by changes in blood volume and glomerular blood flow. ACTH attains a more prominent role in the control of aldosterone secretion when the renin-angiotensin system is suppressed.

The zona glomerulosa also secretes 18-hydroxycorticosterone, a precursor steroid in the aldosterone biosynthetic pathway. This steroid also has mineralocorticoid properties, but is usually present in the circulation in extremely low concentrations. Mineralocorticoids are also synthesized in the zona fasciculata; DOC is the most potent, but corticosterone and cortisol also have weak mineralocorticoid activity. All of these steroids are synthesized as products of the glucocorticoid pathway.

Synthesis of Adrenal Androgens

The zona fasciculata and zona reticularis produce and secrete 17α-hydroxypregnenolone, the main precursor of the adrenal androgens. A microsomal 17α-hydroxylase/C-17,20-lyase ($P\text{-}450_{C17}$) enzyme converts 17α-hydroxypregnenolone to DHEA, which is then converted to DHEA-S by a sulfokinase. 17α-Hydroxyprogesterone can also be converted to androstenedione by this same 17α-hydroxylase/C-17, 20-lyase enzyme. Androstenedione is also derived from DHEA through the action of the 3β-hydroxysteroid dehydrogenase:Δ^5-ketosteroid isomerase complex. DHEA-S and DHEA are the most abundant adrenal-derived androgens.[20]

The adrenal cortex also secretes small quantities of the estrogenic steroids (C_{18} steroids).[185] However, 17β-estradiol and estrone are largely derived from the gonads and from peripheral conversion of testosterone and androstenedione by the aromatase enzyme located in other tissues, such as fat and the liver.

Circulating Forms

Steroid hormones circulate in blood either as free hormones or bound to carrier proteins, such as α_2-globulin corticosteroid-binding globulin (CBG), albumin, or sex hormone-binding globulin (SHBG).[198] Some steroids are conjugated to glucuronide or sulfate and thus circulate independent of a protein carrier. The excretion of steroids occurs via the kidneys or gastrointestinal tract, where they can be reabsorbed. CBG, albumin, and SHBG are produced by the liver (see Chapter 20). CBG and SHBG concentrations are increased by estrogens and in some patients with hepatitis and reduced by glucocorticoids, testosterone, and in patients with liver and kidney disease. At physiological concentrations, about 90% to 98% of steroid hormones circulate bound to a carrier protein, usually with high affinity for a binding globulin, such as CBG and SHBG. At higher physiological concentrations, albumin, which has a high capacity but low affinity for steroids, becomes a more important transport medium for steroids. When a steroid has low affinity for a "carrier protein," 60% to 70% of the steroid circulates bound principally to albumin.[198] Some steroids, such as aldosterone, have a relatively high affinity for CBG, but CBG is not a major carrier protein because cortisol, corticosterone, and 17α-hydroxyprogesterone far exceed the concentration of aldosterone. Similarly, testosterone and dihydrotestosterone circulate primarily bound to SHBG in men, whereas estradiol, despite high binding affinity for SHBG, is bound largely to albumin because its concentration is low relative to that of testosterone. DHEA-S and DHEA circulate primarily bound to albumin, and neither CBG nor SHBG is important in the transport of these adrenal androgens. Prednisolone is the only synthetic glucocorticoid with high binding affinity for CBG, whereas dexamethasone, methylprednisolone, and triamcinolone acetonide are primarily bound to albumin.[198]

One function of both CBG and SHBG is to serve as a circulating storage reserve for steroid hormones and to protect steroid hormones from inactivation. The binding constant for steroids with their respective binding globulins is relatively close to that of the tissue receptor. The biologically active fraction of steroid hormones is still somewhat controversial. There is general agreement that the free fraction and the albumin-bound fraction are readily available for steroid receptor uptake by tissue. This is sometimes referred to as the bioavailable steroid or as the free and weakly bound steroid. Steroids specifically bound to CBG or SHBG are considered to be biologically unavailable because of their high binding affinity to these carrier proteins.[9,61,177] This concept of hormone availability, however, is continuously

being challenged. Some tissue have plasma membrane receptors that can bind the carrier protein–hormone complex. SHBG bound to dihydrotestosterone can activate the membrane signaling mechanism in prostate cells, increasing cyclic adenosine monophosphate (cAMP) formation and mitogenesis.[151] In addition, CBG and SHBG may have a function in tissues that have receptors for cortisol or dihydrotestosterone, respectively. Thus sex steroid hormones appear to act on tissue through two distinct structures, steroid receptors and R_{SHBG}. It has now been suggested that crosstalk occurs between membrane receptors and intranuclear receptors as part of the steroid mechanism of action. The measurement of SHBG-bound steroids may be an important part of interpreting steroid concentrations in states of deficiency and excess.

METABOLISM

The liver is the principal site for the transformation and conjugation of steroid hormones, largely through the enriched presence of the cytochrome P-450 metabolizing enzyme systems; however, the kidneys also play an important role in steroid metabolism. Approximately 90% of conjugated steroids released by the liver are excreted by the kidney and about 50% of secreted cortisol appears in the urine as tetrahydrocortisol (THF) and tetrahydrocortisone (THE). Many tissues contain the necessary enzymes that can activate steroids or render them biologically inactive.[135] Cortisol, for example, is metabolized to cortisone through the activity of 11β-hydroxysteroid dehydrogenase; this change renders this steroid incapable of binding to the glucocorticoid receptor. The liver, however, can convert cortisone back to cortisol, which is biologically active. 17α-Hydroxyprogesterone can be metabolized to 11-DOC, a relatively potent mineralocorticoid in nonsteroid-synthesizing tissue. Androgens such as DHEA and androstenedione can be converted to testosterone in fat tissue and then to dihydrotestosterone in tissues containing the 5α-reductase enzyme. The aromatase enzyme converts testosterone and androstenedione to estradiol and estrone, respectively, in tissues such as fat and the liver. Even sulfated and glucuronidated steroids can be activated by the action of the enzymes sulfatase and β-glucuronidase.[209] Macrophages, for example, can convert DHEA-S to DHEA, which alters cytokine production by associated T lymphocytes. Testosterone is a potent androgen in muscle, a tissue that has little 5α-reductase activity. In skin and prostate tissue, with high Δ^4-5α-reductase activity, testosterone is a prohormone for dihydrotestosterone, the active androgen in these tissues.[58,204] Thus considerable metabolism of steroids takes place outside of their original site of synthesis.

Cortisol

An understanding of the metabolism of cortisol is important in interpreting tests designed to evaluate alterations in cortisol production rates and disorders of adrenal function.[135] Less than 2% of cortisol is excreted unchanged in the urine. As a result of its tight binding to CBG, cortisol is metabolized slowly ($t_{1/2}$ ~ 100 minutes). In the liver, metabolism of cortisol involves reduction of the double bond between C-4 and C-5 by Δ^4-5β- or Δ^4-5α-reductase to form dihydrocortisol or dihydrocortisone. Further metabolism of cortisol and cortisone produces THF and THE, respectively, which are in turn metabolized to the cortoic acids, cortol, and cortolone (Figure 51-7). A minor metabolite of cortisol is 6β-cortisol, which appears unconjugated in the urine. More than 95% of the metabolites of cortisol and cortisone are conjugated by the liver; glucuronidation at the 3α-hydroxyl position is favored over the other hydroxyl groups, and the 21-hydroxyl group is favored for sulfations; glucuronide metabolites are more abundant than sulfated steroids.

Androgens

Adrenal androgens also have a complex metabolic fate; DHEA-S is formed in the adrenal cortex or by sulfokinases in the liver and kidney from DHEA and excreted by the kidney.[129] DHEA and DHEA-S can be metabolized by 7α- and 16α-hydroxylases. 17β-Reduction of both compounds forms Δ^4-5-androstenediol and its sulfate. Androstenedione can be metabolized to androsterone after 3α- and 5α-reduction. 5β-Reduction results in the formation of etiocholanolone (see Figure 51-7). These metabolites are conjugated to glucuronides and sulfates, which are then excreted in the urine.

Factors Affecting Metabolism

Liver, kidney, and thyroid disease affect the secretion and metabolism of the adrenal steroids. Other factors affecting these processes include stress, age, estrogen therapy, nutrition, and drugs.

Liver Disease

Chronic liver disease reduces cortisol clearance and the production of urinary metabolites. Cortisol concentrations are elevated by acute ingestion of alcohol. Individuals with alcoholic cirrhosis have normal to elevated basal cortisol concentrations, blunted circadian rhythms, and prolonged clearance rates.

Kidney Disease

In patients with chronic renal failure, plasma concentrations of total and free cortisol and ACTH are usually normal. Plasma-conjugated metabolites of cortisol are elevated, and renal excretion, as expected, is reduced. ACTH stimulation (4 hours) produces normal to slightly exaggerated responses of cortisol, DHEA-S, and aldosterone and normal responses of DHEA-S and androstenedione.

Thyroid Disease

Hypothyroidism reduces and hyperthyroidism increases both the secretion and metabolism of cortisol without substantially affecting its blood concentrations. Thyroid hormone alters 11β-hydroxysteroid dehydrogenase activity

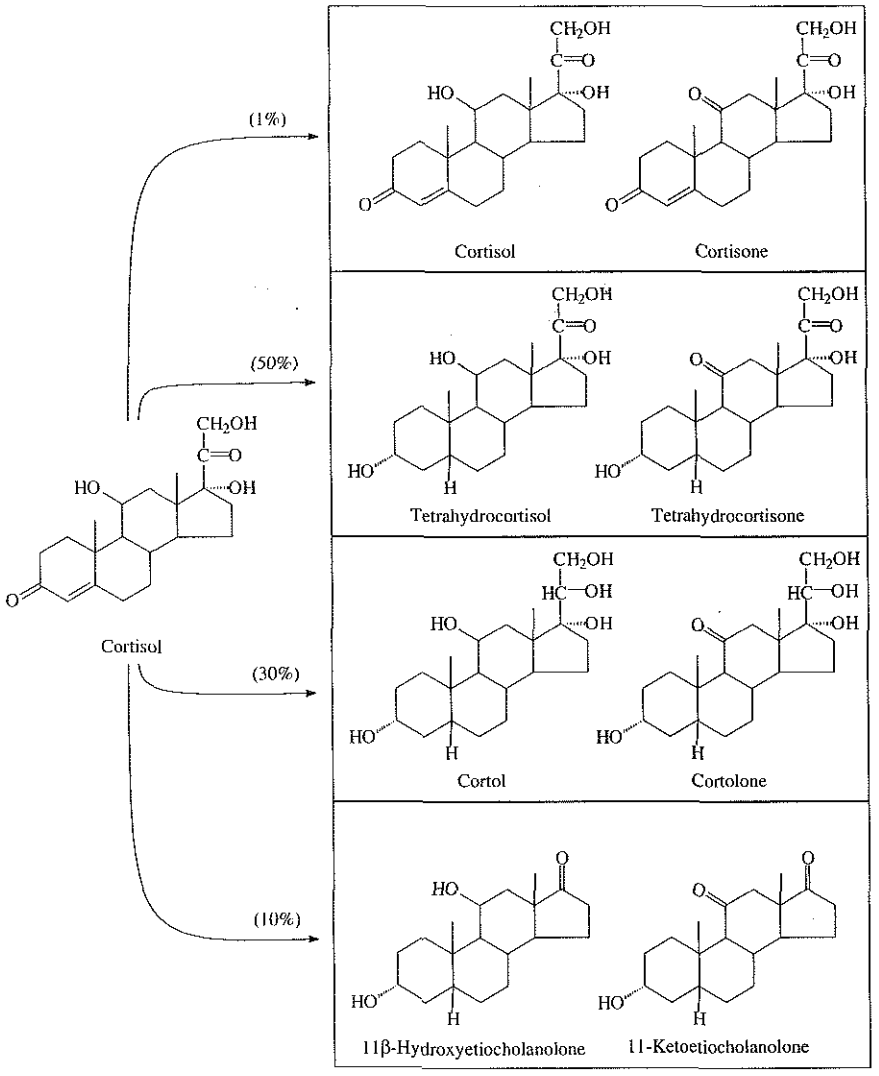

Figure 51-7 Schematic drawing of the major urinary metabolites of cortisol showing the approximate extent of conversion and the metabolites as determined by different methods. *(From James VHT, Landon J. In: Recent advances in endocrinology, 8th ed. Boston: Little, Brown & Co Inc, 1968.)*

that converts cortisol to cortisone. In hyperthyroidism, 11-ketometabolites, tetrahydrocortisone, and cortolones are favored; in hypothyroidism, tetrahydrocortisol and cortols predominate. Hypothyroidism decreases the concentrations of DHEA and DHEA-S. 5α-Reductase activity is reduced, which leads to the formation of more androsterone relative to etiocholanolone.

Stress

Acute stress from trauma or illness elevates the concentrations of both adrenal glucocorticoids, cortisol and corticosterone, and the adrenal androgens DHEA and DHEA-S. Chronic illness elevates plasma cortisol concentrations but suppresses DHEA, DHEA-S, and androstenedione concentrations.

Age

The newborn produces more cortisone than cortisol. A few days after birth, cortisol production predominates in a pattern similar to that of adults. Neonates lack 5α-reductases and have deficient glucuronyl transferase and therefore produce more 6β-hydroxylated metabolites of cortisol than adults.[134] Circulating concentrations of cortisol and CBG remain constant after the neonatal period. In old age, both the production and metabolic clearance rates of cortisol are about 25% lower than in younger adults. Urinary excretion of cortisol and other 17-hydroxyl metabolites decreases with age, but ACTH stimulation of cortisol remains normal in the elderly.

Age and familial factors in both men and women influence both plasma adrenal androgens (DHEA and DHEA-S). Adrenal androgen secretion starts to rise about the age of 9, peaks at about age 25, and declines after age 30.[170] In the seventh decade of life, the adrenal androgen concentrations fall to prepubertal concentrations. Thus in the elderly, the circadian variation in plasma DHEA is relatively blunted and dissociated from the circadian variation in cortisol. The adrenal contribution of serum androstenedione declines with age.[108] DHEA and DHEA-S responses to stimulation with exogenous ACTH are

decreased in the elderly, but the androstenedione response is minimally affected.[108,141]

Estrogen Therapy

Estrogens increase the plasma concentrations of CBG and thus markedly influence total cortisol blood concentrations. The concentration of free cortisol is unaffected; the clearance of cortisol and its production rate and concentrations of urinary metabolites are subnormal with estrogen therapy.

Nutrition

Obesity elevates the urinary conjugated metabolites of cortisol thus erroneously suggesting the diagnosis of Cushing's syndrome. The measurement of urinary free cortisol, which is not influenced by obesity, is therefore recommended when screening for Cushing's syndrome. Plasma concentrations of total and free cortisol and urinary free cortisol excretion rates in obesity are all normal.[174] Dexamethasone suppression of adrenal function is also normal. However, cortisol responses to exogenous ACTH are increased, suggesting adrenocortical hyperplasia. Obesity also can elevate the adrenal androgens DHEA and DHEA-S and androstenedione production and clearance rates.[41,152] Plasma concentrations of these steroids are elevated in obese children during pubertal development but not in obese adults.

Starvation is associated with a decrease in both the production and clearance rates of cortisol. In patients with anorexia nervosa, despite reductions in urinary excretion of cortisol metabolites, plasma concentrations and urinary excretion of cortisol may be elevated.[135] The responses of cortisol to dexamethasone are blunted in many patients with anorexia nervosa, but cortisol responses to ACTH in these patients are normal.

Drugs

Hepatic mixed-function oxidases are induced by many drugs, including phenytoin, phenobarbital, mitotane, aminoglutethimide, and rifampin. In addition, 6β-hydroxylase and other drug-metabolizing pathways that metabolize cortisol and other steroids are increased by a number of drugs. Urinary excretion rates of cortisol metabolites are reduced, but plasma cortisol concentrations and urinary free excretion rates of cortisol are not affected. The metabolism of synthetic glucocorticoids, prednisolone, and dexamethasone is markedly increased by drugs that induce the hepatic hydroxylase enzyme systems. Dexamethasone suppression test results and metyrapone test results are also altered. Knowledge of the patient's drug history is important for the proper interpretation of tests that validate the integrity of the pituitary-adrenal axis.

The Hypothalamic-Pituitary-Adrenal Cortical Axis

Secretion of adrenal glucocorticoids and androgens is regulated by ACTH (see Chapter 50), which in turn is under the control of the hypothalamic peptide, corticotropin-releasing hormone (CRH).[169,211] The pituitary gland also has been found to secrete a separate hormonal factor that specifically regulates adrenal androgen production.[141] This substance, called cortical androgen-stimulating hormone, has been identified as a glycopeptide in human pituitary extracts and shows sequence homology to an 18–amino acid *N*-terminal component of pro-opiomelanocorticotropin, the precursor peptide of ACTH and of melanocyte-stimulating hormone. The HPA relationships in health and in various adrenal disorders are depicted in Figure 51-8.

Regulation of Adrenal Hormones

Adrenocorticotropic Hormone Secretion

Biorhythms and other physiological events in the brain result in episodic and circadian secretion of CRH from the hypothalamus. This in turn elicits similar circadian variation in ACTH release.[50,76,135] Secreted ACTH then stimulates cortisol production, which provides negative feedback inhibition to the CRH-ACTH axis.[169] The secretion of CRH, a 41–amino acid peptide, is modulated by neuroendocrine, physical, and emotional factors.[169] Besides CRH, other circulating factors can have an influence on the secretory dynamics of ACTH release. Antidiuretic hormone from the

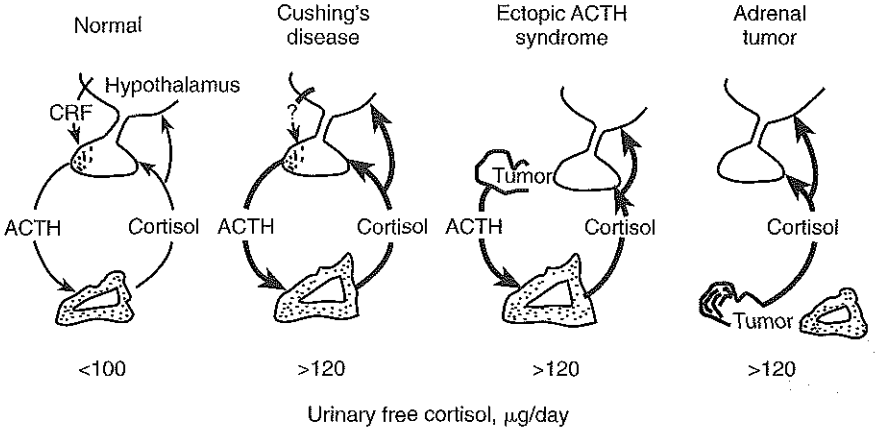

Figure 51-8 HPA under normal conditions and in various adrenal disorders. *ACTH,* Adrenocorticotropic hormone; *CRF,* corticotropin-releasing factor. *(From Lipsett MB, Odell WD, Rosenberg LE. Humoral syndromes associated with nonendocrine tumors. Ann Intern Med 1964;61:733. Copyright 1964, American Medical Association.)*

posterior pituitary and other peptides (angiotensin II, activin, cytokines, opiates, and somatostatin) and catecholamines influence the secretion of ACTH from the adenohypophysis.[46,156]

The circadian rhythm of ACTH secretion under normal wake and sleep cycles produces higher cortisol concentrations in the morning between 0400 and noon and lower concentrations in late evening and early morning.[135] The magnitude of the morning cortisol concentration is affected by familial and genetic factors.[109]

Trauma, fever, surgery, hypoglycemia, alcohol ingestion, uncontrolled diabetes, and nutritional deprivation, including that associated with anorexia nervosa, are physical stresses that elevate plasma cortisol concentrations and alter the circadian rhythm.[169] Major depression and severe anxiety are psychological stresses that also elevate plasma cortisol concentrations. ACTH secretion in response to minor stresses is inhibited by the administration of exogenous glucocorticoids. Major stress responses such as surgery, however, result in cortisol secretion unresponsive to glucocorticoid suppression. Cortisol secretion is suppressed by glucocorticoids in lesser forms of stress, such as minor surgery, exercise, or hypoglycemia.

Prolonged suppression of ACTH by administration of glucocorticoids causes atrophy of the adrenal cortex.[135] The degree of atrophy is related to the duration and magnitude of suppression of ACTH secretion. With prolonged intense suppression, recovery of the HPA axis can take several days to a few months.

Cortisol Secretion

ACTH has both trophic and steroidogenic effects on the adrenal cortex and is under negative feedback control from nonprotein-bound cortisol.[169] ACTH binds to a G protein–coupled, melanocortin-2 receptor at the membrane of each adrenocortical cell with signal transduction mediated via cAMP. Cortisol is secreted within a few minutes after a rise in serum ACTH through a StAR-mediated increase in cholesterol delivery to the desmolase enzyme located in the inner mitochondrial membrane. Chronic exposure to ACTH results in increased synthesis of all steroidogenic enzymes through gene activation at the nuclear concentration. Deficiency of ACTH results in atrophy of the zona fasciculata and zona reticularis. With atrophy of the adrenal cortex from various causes and reduced cortisol synthesis and release, plasma ACTH concentrations rise. Other modifying factors such as age, various diseases, estrogen therapy, nutrition, general illness, and drugs also affect cortisol secretion. Both hypertrophy and hyperplasia of the adrenal cortex occur in response to chronic exposure to ACTH. The trophic response to ACTH can be reproduced by cAMP stimulation of insulin-like growth factor-II rather than cAMP directly.[135]

The proinflammatory cytokines including IL-1, IL-6, and TNFα also increase cortisol secretion through an increase in pituitary ACTH secretion as part of the important immune-endocrine interaction that occurs with disease and infection (see Chapter 22).

Adrenal Androgen Secretion

The adrenal cortex secretes DHEA (~4 mg/day), DHEA-S (10 mg/day), androstenedione (1.5 mg/day), and testosterone (0.05 mg/day) as components of the adrenal androgen pathway. ACTH partially regulates adrenal androgen production in adults; both DHEA and androstenedione are secreted in conjunction with cortisol.[141] Adrenal androgen production begins to rise in late childhood about the age of 9 just months before the onset of puberty, reaches a peak in the third decade of life, and then gradually decreases, reaching low concentrations again in advanced age.[20] Glucocorticoid therapy also suppresses the secretion of adrenal androgens.[106,141] The secretion of cortisol and adrenal androgens, however, can be dissociated, particularly in children, adolescents, and the elderly. The explanation for the dissociation is unclear, although it lends credence to the suggestion that an independent factor from the pituitary gland, such as cortical androgen-stimulating hormone, can stimulate adrenal androgen production independent of ACTH.[141] In young children, the low adrenal androgen concentrations are not further suppressed by glucocorticoid therapy.

Aldosterone Secretion

The primary control mechanism for the secretion of aldosterone involves the renin-angiotensin system although potassium and to a lesser extent ACTH can also promote secretion of aldosterone from the zona glomerulosa. *Renin* is a proteolytic enzyme synthesized and stored in specialized cells, the *juxtaglomerular epithelial cells,* located along the terminal part of the afferent arterioles of the renal glomeruli.[6,121] These specialized cells constitute part of the juxtaglomerular apparatus. Upon stimulation of the juxtaglomerular apparatus, renin is released into the circulation, where it hydrolyzes its substrate, angiotensinogen, to produce a decapeptide known as *angiotensin I.* Angiotensinogen is a globulin synthesized in the liver. Angiotensin I is then rapidly converted to an octapeptide, *angiotensin II,* by a circulating *angiotensin-converting enzyme,* which is found in abundance in the lung. Angiotensin II is a potent vasoconstrictor and stimulates the cells of the zona glomerulosa to produce aldosterone. Angiotensin II stimulates aldosterone secretion by increasing the transcription of CYP11B2, the gene responsible for aldosterone synthase through common intracellular signaling pathways. Potassium, on the other hand, stimulates aldosterone synthesis and release through a membrane depolarization effect that opens up calcium channels in adrenal cells to activate cell signaling mechanisms such as phospholipase C, leading to an increase in aldosterone synthase synthesis and release. The primary stimuli for renin release are a decrease in renal arteriolar pressure, oncotic pressure, and an increase in sympathetic drive to the macula

densa of the juxtaglomerular apparatus and a negative sodium balance. Stimulation of renin release and aldosterone secretion under different physiological and pathological conditions is discussed later. ACTH also increases aldosterone secretion. However, the size and function of the zona glomerulosa are affected primarily by the renin-angiotensin system and potassium. Hyperplasia results when concentrations of angiotensin II or K^+, or both, are elevated, and atrophy occurs with a deficiency of angiotensin II or with defects in its actions.

Testing the Functional Status of the Adrenal Cortex

Concentrations of hypothalamic and anterior pituitary peptides and adrenal glucocorticoids are measured accurately and at low concentrations in body fluids using immunoassay and instrumental methods. Relying on basal hormone concentrations for confirming adrenocortical dysfunction, however, can be problematic because of the episodic and circadian secretion of the hormones that regulate the HPA axis. For example, some individuals have an abnormality of the HPA axis, but still maintain basal cortisol and ACTH secretion within the reference interval of the normal population. Dynamic testing of the HPA axis helps define abnormalities that are not reflected in basal hormone secretion.

Corticosteroid Function

Basal Peptide and Steroid Hormone Concentrations

Episodic secretion and circadian variation limit the clinical diagnostic accuracy of basal serum cortisol concentrations. Serum cortisol concentrations are highest in the early morning hours and varies from 5 to 25 µg/dL between 0400 and 1200 hours. Late afternoon values are about half the morning concentrations and are frequently less than 5 µg/dL between 2200 and 0200 hours. Serum cortisol combined with plasma ACTH improves the diagnostic accuracy of basal values.

Urinary free cortisol obtained from a 24-hour urine collection is an integrated measure of plasma free cortisol and eliminates the circadian influence on cortisol secretion. Urine free cortisol measurements are therefore considered to be the best screening test for hyperadrenocorticism. The urinary free cortisol excretion rate in normal subjects falls between 20 and 80 µg/day (Figure 51-9). The measurement of urinary 17-hydroxycorticosteroid excretion rates for determining adrenocortical hyperfunction is no longer recommended because of problems with method sensitivity and specificity.

Mineralocorticoid and adrenal androgen secretion is also circadian and episodic in nature, but the dynamic swings in concentrations are not as pronounced as with cortisol. It is usually recommended, however, that blood samples for adrenal steroids be collected in the 0700 to 1000 hour time frame for consistency in result interpretation.

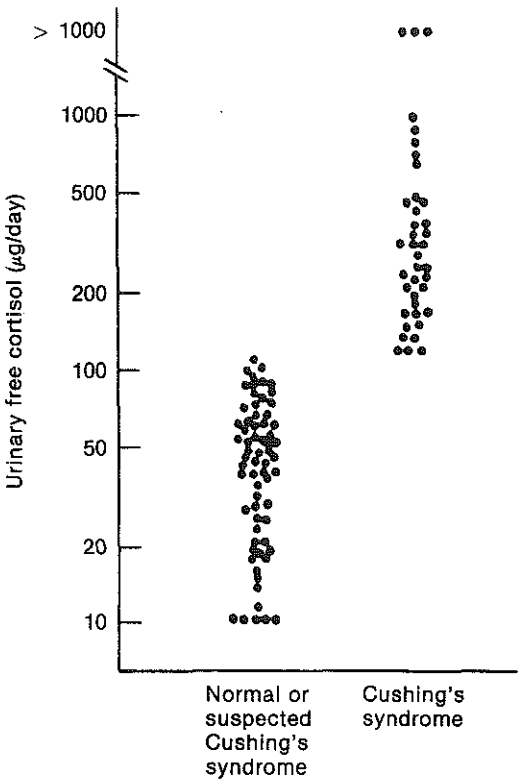

Figure 51-9 Urinary free cortisol excretion in normal individuals with Cushing's syndrome. *(From Burke CW, Beardwell CG. Cushing's syndrome. An evaluation of the clinical usefulness of urinary free cortisol measurements in screening for Cushing's syndrome. Q J Med 1973;42:1175.)*

Stimulation Tests of Adrenal Function

Provocative stimulation tests are useful in documenting hyposecretion of adrenocortical hormones.[135] A specific stimulus is applied, and the release of a given hormone is measured in a specific time frame. *ACTH stimulation tests,* sometimes referred to as the cosyntropin test, are designed to document the functional capacity of the adrenal glands to synthesize cortisol (Boxes 51-1 and 51-2). In healthy individuals, the administration of exogenous ACTH rapidly increases the secretion of cortisol by twofold to threefold within 60 minutes of the applied stimulus. This functional response may be impaired either by adrenal atrophy, caused by a chronic deficiency of ACTH, or by primary destruction of the adrenal cortex. The biologically active 1-24 amino acid sequence of human ACTH has been synthesized and is available as tetracosactrin (Synacthen). This compound is a potent stimulant for cortisol secretion and has a very brief half-life and minimal antigenicity. A peak plasma cortisol concentration >20 µg/dL (525 nmol/L) within 60 minutes of the intravenous administration of Synacthen is defined as a normal response.

A direct and selective test of pituitary gland function is the *CRH stimulation test* (Box 51-3).[93] Injection of ovine CRH stimulates ACTH secretion in normal subjects within

BOX 51-1 Protocol for the Rapid Adrenocorticotropic Hormone (ACTH) (Synacthen) Test

Rationale The administration of ACTH to normal subjects results in a rapid rise in the serum cortisol concentration. Patients with adrenal destruction (Addison's disease) show no change in serum cortisol concentration after ACTH administration. Patients with atrophy of the adrenal cortex caused by exogenous glucocorticoid treatment or dysfunction of the pituitary gland or hypothalamus may show a slight rise in serum cortisol concentration, but not one of normal magnitude.

Procedure A baseline blood sample is drawn for determination of serum cortisol concentration; then 250 μg of Synacthen (1-24 ACTH) is given intramuscularly or intravenously. Further samples for serum cortisol determination are drawn 30 and 60 minutes after injection.

Interpretation A peak serum cortisol concentration of >20 μg/dL is a normal response. The peak value is more important than the incremental change. The incremental change may not be seen in patients who are tested at times of stress, when their adrenal output of cortisol is already maximally stimulated by endogenous ACTH.

BOX 51-2 Protocol for the Multiple-Day Adrenocorticotropic Hormone (ACTH) Stimulation Test

Rationale Multiple-day ACTH stimulation testing for assessment of adrenal cortex function is required occasionally to evaluate adrenal cortisol responsiveness. A common situation is the diagnosis of adrenal insufficiency, which is treated with glucocorticosteroids before establishment of an etiology. Prolonged ACTH stimulation is also used to distinguish primary from secondary and/or tertiary causes of adrenal insufficiency.

Procedure ACTH gel, 80 U/day, is injected for 3 days. This is followed by a standard 8-hour infusion of ACTH (250 μg of Synacthen over 8 hours). Urinary free cortisol and serum cortisol are measured daily.

Interpretation Serum cortisol values more than 20 μg/dL exclude primary adrenal insufficiency. Glucocorticoid withdrawal would be required before assessing secondary or tertiary adrenal insufficiency in such cases. Little or no increase in cortisol secretion is seen in primary adrenal failure even over successive days. A progressive staircase rise is seen over 2 to 3 days in adrenal insufficiency caused by pituitary or hypothalamic disease or steroid concentration suppression. Little or no response is also seen in congenital adrenal hyperplasia (CAH) caused by 21- and 17-hydroxylase deficiencies.

BOX 51-3 Protocol for the Corticotropin-Releasing Hormone (CRH) Stimulation Test

Rationale Exogenous CRH stimulates the secretion of ACTH from the anterior pituitary gland in normal subjects. Cortisol concentration is an indicator of ACTH response.

Procedure Synthetic ovine CRH (preferred) or human CRH (1 μg/kg body weight) is administered intravenously in bolus form at either 0900 or 2000 hours. Blood samples for cortisol and ACTH assays are collected 15 minutes and immediately before and 5, 15, 30, 60, 120, and 180 minutes after CRH injection.

Interpretation In normal subjects, plasma ACTH concentrations peak 30 minutes after CRH injection (80 ± 7 pg/mL at 0930 hr; 29 ± 2.6 pg/mL at 2030 hr), and serum cortisol peaks at 60 minutes (13 ± 1 μg/dL at 1000; 17 ± 0.7 μg/dL at 2100 hr). Patients with pituitary ACTH deficiency (secondary adrenal insufficiency) have decreased ACTH and cortisol responses. Patients with hypothalamic disease have prolonged ACTH responses and subnormal cortisol responses. Most patients with Cushing's syndrome caused by adrenal tumors or nonendocrine ACTH-producing tumors do not respond to CRH. Most patients with Cushing's syndrome respond with a normal or excessive increase in ACTH. Responses are usually normal in patients with depression.

60 to 180 minutes; glucocorticoids inhibit this effect. The use of this test is in the differential diagnosis of adrenocortical hyperfunction and hypofunction. This test is also used in the differential diagnosis of endogenous Cushing's syndrome and to distinguish secondary from tertiary ACTH deficiency.[42]

A variation of the CRH stimulation test measures ACTH in blood samples drawn from the inferior petrosal sinus (IPS) both to document the presence of a pituitary microadenoma and to determine on which side of the pituitary the microadenoma is located. Blood samples are collected from both right and left IPS veins and from a peripheral vein before and 2, 5, and 10 minutes after the intravenous administration of ovine CRH (1 μg/kg body weight) over 20 to 60 seconds. The ratio of the IPS concentration to peripheral venous concentration of plasma ACTH is used to predict the location of excess corticotropin secretion. As shown in Figure 51-10, the maximum ratio is >3 in patients with pituitary Cushing's syndrome and <3 in those with the likelihood of an ectopic ACTH syndrome or an adrenal tumor. Some endocrinologists claim that IPS sampling is the best test for distinguishing ACTH-dependent forms of Cushing's syndrome when performed in the setting of prolonged hypercortisolism. ACTH concentrations are suppressed in patients with primary adrenal tumors compared with those with either Cushing's syndrome or the ectopic ACTH syndrome.

To test the integrity of the pituitary-adrenal axis, other indirect tests of ACTH secretion rely on the adrenal response

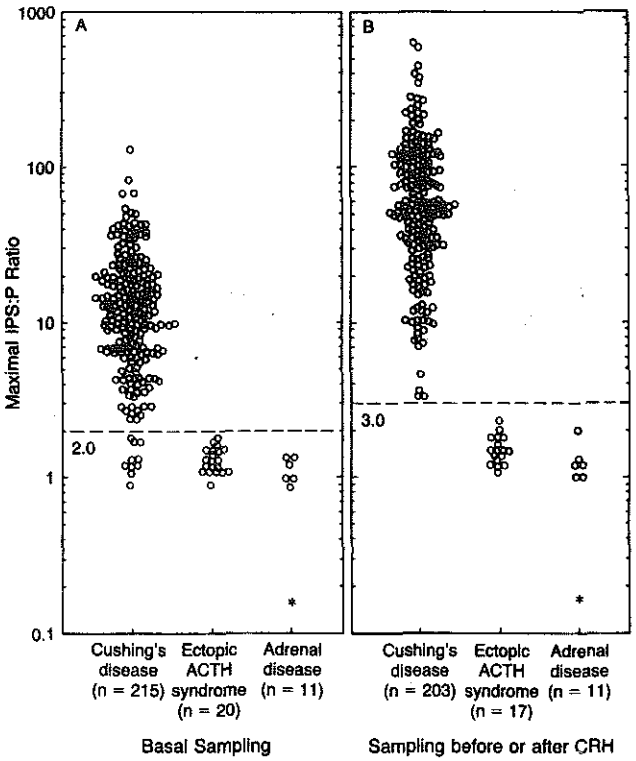

Figure 51-10 Inferior petrosal sinus-to-peripheral venous (IPS:P) plasma ACTH ratios in patients with Cushing's syndrome during basal sampling (*panel A*) and either during basal sampling or 2 or 5 minutes after ovine corticotropin-releasing hormone (oCRH) administration (*panel B*). During basal sampling, the maximum ratio was ≥2.0 in 205 of 215 patients with confirmed Cushing's syndrome and <2.0 in 20 patients with ectopic ACTH syndrome and 11 patients with adrenal Cushing's syndrome. All of the 203 patients who had confirmed Cushing's syndrome and who received oCRH had a maximum IPS:P ratio >3.0 in one of the basal sample sets or in one of the post-oCRH sample sets, whereas all of the 17 patients with ectopic ACTH syndrome and the 11 patients with adrenal Cushing's syndrome who received oCRH had a ratio <3.0. The *asterisks* represent five patients in whom immunoreactive ACTH was undetectable in peripheral plasma before and after oCRH administration. *(From Oldfield EH, Doppman JL, Nieman LK, Chrousos GP, Miller DL, Katz DA, et al. Petrosal sinus sampling with and without corticotropin-releasing hormone for the differential diagnosis of Cushing's syndrome. N Engl J Med 1991;325:897-905.)*

to maneuvers that stimulate endogenous ACTH release. In the *insulin-induced hypoglycemia stimulation test,* insulin is given to stimulate the release of CRH through hypoglycemia, and plasma ACTH or cortisol concentrations are evaluated for an increase (see Box 50-3; Chapter 50). This test involves risks and should be performed only with an experienced physician in attendance.

A less risky indirect test of HPA axis function involves the administration of metyrapone, an inhibitor of the 11β-hydroxylase enzyme that converts 11-deoxycortisol to cortisol. In normal individuals, the fall in the plasma cortisol concentration that accompanies the metyrapone-induced

BOX 51-4 Protocol for the Overnight Single-Dose Metyrapone Stimulation Test

Rationale Metyrapone inhibits 11β-hydroxylase, the enzyme that catalyzes the step immediately preceding cortisol synthesis. As the blood concentration of cortisol falls, the negative feedback effect is diminished, causing release of ACTH from the pituitary gland. The stimulatory effect of ACTH on the adrenal cortex leads to a rise in 11-deoxycortisol, the compound immediately preceding cortisol in the biosynthetic pathway.

Procedure Metyrapone (30 mg/kg body weight) is given orally at midnight with milk or a snack (to delay absorption). At 0800 hours the following morning, blood is drawn for determination of 11-deoxycortisol, cortisol, and ACTH concentrations.

Interpretation In normal subjects, 11-deoxycortisol increases from <1 μg/dL to >7 μg/dL after metyrapone stimulation, and ACTH values exceed 150 pg/mL. No response or impaired response may be seen in pituitary or hypothalamic disease combined with inadequate enzyme blockade (plasma cortisol >3 μg/dL) or with Cushing's syndrome caused by adrenal tumors or nonendocrine ACTH-secreting tumors. Exaggerated responses may be seen in pituitary Cushing's syndrome.

enzyme block stimulates pituitary ACTH release, and adrenal steroid precursors then accumulate to the point of the enzyme block. Under normal circumstances, 11-deoxycortisol (compound S), the steroid substrate for the 11β-hydroxylase enzyme, increases fortyfold to eightyfold within 3 hours after metyrapone administration. The lack of an increase suggests primary adrenal failure. Several protocols have been designed for *metyrapone stimulation testing;* one that is simple and relatively safe for outpatient testing is described in Box 51-4.

Suppression Tests

Suppression tests are used to document hypersecretion of the adrenocortical hormones.[135] In normal individuals, an elevation in the blood concentration of cortisol inhibits ACTH release from the pituitary gland. This results in decreased production of cortisol and other adrenal steroids from the adrenal cortex. The integrity of this feedback mechanism can be tested by administering a potent glucocorticoid, such as dexamethasone, and judging suppression of ACTH secretion by measuring serum or urine cortisol concentrations. A number of *dexamethasone suppression tests* are available for clinical use (Boxes 51-5 through 51-8). A low dose of dexamethasone is used initially to document true hypersecretion of cortisol.[207] Patients with Cushing's syndrome of any cause will fail to suppress their cortisol secretion overnight with a low dose of dexamethasone. Higher doses of dexamethasone given over 48 hours are then used to establish the differential diagnosis of an ACTH-secreting pituitary adenoma as distinct from an ectopic ACTH source. A >50% suppression of plasma cortisol in comparison with

BOX 51-5 Protocol for the Overnight Low-Dose Dexamethasone Suppression Test

Rationale Dexamethasone, a cortisol analogue, suppresses ACTH and cortisol production in normal subjects but not in patients with Cushing's syndrome.

Procedure One milligram of dexamethasone is given orally at 2300 or midnight. Blood is drawn for determination of serum cortisol at 0800 hours on the next morning.

Interpretation In normal subjects, serum cortisol concentration is suppressed to 2 μg/dL or less after administration of 1 mg of dexamethasone. Most patients with Cushing's syndrome do not show adequate suppression, and 0800 hours cortisol concentrations are usually >10 μg/dL. Serum cortisol >2 μg/dL may also be seen in cases of stress, obesity, infection, acute or chronic illness, alcohol abuse, severe depression, oral contraceptive use, pregnancy, estrogen therapy, failure to take the dexamethasone, or treatment with phenytoin or phenobarbital (enhancement of dexamethasone metabolism).

BOX 51-6 Protocol for the Multiple Low-Dose Dexamethasone Suppression Test

Rationale Normal subjects show lowering of serum and urinary free cortisol concentrations under the conditions of low-dose dexamethasone suppression. Patients with excess cortisol production regardless of etiology usually show persistent elevation of cortisol under these conditions.

Procedure Twenty-four-hour urine samples are collected daily for 4 consecutive days. Dexamethasone, 0.5 mg, is given orally every 6 hours starting at 0800 hours on day 2 (for a total of 8 doses). Free cortisol, 17-hydroxycorticosteroids, and creatinine are measured in each 24-hour urine sample. Other measurements include serum cortisol determinations on day 1 (at 0800 hours and 2000 hours) to look for diurnal variation and on day 5 (at 0800 hours).

Interpretation Normal subjects have suppressed serum and urinary free cortisol concentrations on day 4 to <50% of baseline values; serum cortisol at 2000 hours on day 1 should be one third of the value at 0800 hours. Patients with Cushing's syndrome usually do not show diurnal rhythmicity and do not show suppression with low-dose dexamethasone. Those patients taking phenytoin or phenobarbital, or both, metabolize dexamethasone more rapidly than do normal subjects and may not show suppression.

the original basal result defines a positive response. Patients with an ectopic ACTH-producing tumor will fail to suppress with high-dose dexamethasone. Abnormal suppression of cortisol by dexamethasone has been observed in patients with depression, severe stress, uncontrolled diabetes mellitus, or anorexia nervosa; with estrogen administration, and in subjects receiving medications, such as phenytoin, that induce the hepatic enzyme systems that can metabolize the dexamethasone.

BOX 51-7 Protocol for the Multiple High-Dose Dexamethasone Suppression Test

Rationale Patients with Cushing's syndrome caused by an ACTH-producing pituitary adenoma usually show suppression of cortisol with high-dose dexamethasone. Patients with Cushing's syndrome from other causes (adrenocortical adenoma, adrenocortical carcinoma, or ectopic production of ACTH) usually do not demonstrate any change in cortisol concentration.

Procedure Twenty-four-hour urine collections are obtained daily for 4 days for free cortisol and 17-hydroxycorticosteroid determinations. Dexamethasone, 2.0 mg orally every 6 hours, is begun at 0800 hours on day 2 and continued for eight doses. Free cortisol and creatinine are measured in each 24-hour urine sample. Other measurements include plasma cortisol at 0800 hours and 2000 hours on day 1 to look for diurnal variation and at 0800 hours on day 5.

Interpretation Patients with Cushing's syndrome caused by an ACTH-secreting pituitary adenoma usually show (1) suppression of urinary free cortisol and 17-hydroxycorticosteroid excretion ≥50% of baseline by day 4; (2) lack of diurnal variation in plasma cortisol; and (3) plasma cortisol ≤10 μg/dL at 0800 hours on day 5.

BOX 51-8 Protocol for the High-Dose Overnight Dexamethasone Suppression Test

Rationale The rationale for this test is similar to the rationale for the multiple high-dose dexamethasone suppression test (see Box 51-7).

Procedure Dexamethasone, 4 mg, is given orally at 2300 and 2400 hours. Blood is drawn for determination of plasma cortisol at 0700 hours or 0800 hours the next morning or 8 to 9 hours after dexamethasone is given.

Interpretation Most patients with Cushing's syndrome show a suppression of baseline cortisol concentration of at least 50%. If suppression is <50%, the test should be repeated with 8 to 24 mg of dexamethasone.

Mineralocorticoid Function

Basal Peptide and Steroid Hormone Concentrations

Concentrations of adrenal mineralocorticoids (e.g., aldosterone and DOC) and factors of the renin-angiotensin system (e.g., renin) are routinely measured in body fluids by various immunoassay and instrument-based methods.[6] Aldosterone, like cortisol, is secreted episodically, with the highest circulating concentrations at about the time of awakening and the lowest concentrations shortly after sleep onset; aldosterone concentrations, however, are only modestly stimulated by ACTH secretion.[119] In healthy subjects, a low-sodium diet, maintaining an upright posture, and use of diuretics all increase plasma aldosterone concentrations,

whereas a high-sodium diet and lying in the supine position decrease aldosterone secretion. Standardized procedures for obtaining blood and urine specimens are required for proper interpretation of test results.[6] It is also useful to interpret the aldosterone concentrations along with a urinary sodium determination because salt intake can profoundly influence the aldosterone concentration. The aldosterone concentration is inversely proportional to the urinary sodium concentration.

Unlike aldosterone, plasma renin is often measured in terms of its enzymatic activity, although immunometric-based mass assays for renin have become available. *Plasma renin activity* (PRA) is gauged by the generation of angiotensin I, which is measured using immunoassay techniques, and renin mass assays directly measure renin using monoclonal antibodies targeted to the renin enzyme itself. Renin release is controlled by many physiological factors. Low-sodium diets, maintaining an upright posture, and use of diuretic medications increase renin release and should be controlled or eliminated before testing of the renin-angiotensin-aldosterone axis.[21] Because plasma renin activities also vary with sodium balance, it is helpful to interpret ambulatory PRA with urinary sodium excretion. An inverse relationship is found, allowing the identification of low-, normal-, and high-plasma renin groups from a nomogram (Figure 51-11). Age, estrogen therapy, and diabetes mellitus without renal failure affect plasma renin results. Patients older than age 55 and those with diabetes have PRA results that are about 50% of normal. Estrogen causes an increase in the hepatic synthesis of angiotensinogen, thereby increasing the endogenous substrate concentration for the renin enzyme. This causes an inappropriately elevated renin activity for the urinary sodium concentration. A number of medications affect plasma renin activities. Angiotensin converting enzyme (ACE) inhibitors, beta blockers, spironolactone, and nonsteroidal antiinflammatory agents lead the list of drugs that can alter plasma renin.

Even when time of sampling, posture, drug intake, and diet are controlled, it is often difficult to identify disorders of mineralocorticoid secretion on the basis of basal hormone concentrations alone. A variety of dynamic tests have therefore been developed to help document hypersecretion or hyposecretion of aldosterone and renin.

Stimulation Tests

The renin-angiotensin-aldosterone system responds to electrolyte balance. Sodium excretion and extracellular fluid volume are inversely associated with plasma renin and aldosterone concentrations.[21] The sodium-to-creatinine ratio in a urine specimen can be used as a marker for the sodium volume status. Procedures for stimulating the renin-angiotensin system are based on volume-depletion maneuvers, such as sodium restriction, upright posture, or diuretic administration.[6,64] In the *furosemide stimulation test,* oral or intravenous furosemide (40 to 80 mg) is administered, followed by 4 hours of upright posture (Box 51-9). This test does not require hospitalization, special diets, or prolonged standing, although it works better when a diet with normal salt intake is maintained. The normal response to this diuretic is a twofold to threefold rise in plasma renin.

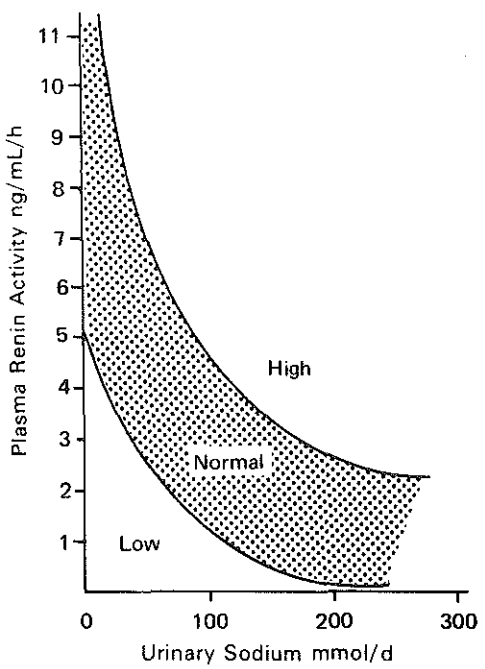

Figure 51-11 PRA correlated to urinary sodium excretion. *(From Laragh JH, Sealey J, Brunner HR. The control of aldosterone secretion in normal and hyperactive man: Abnormal renin and aldosterone patterns in low renin hypertension. Am J Med 1972;53:649.)*

BOX 51-9 Protocol for the Furosemide Stimulation Test

Rationale PRA varies with the state of hydration and sodium intake. The administration of furosemide, a potent diuretic, provides a stimulus to increase plasma renin secretion.

Procedure Furosemide (Lasix; Hoechst-Roussel Pharmaceuticals, Somerville, NJ), 40 to 80 mg, is given orally after an overnight fast. The subject is maintained in an upright posture (sitting, standing, or walking) throughout the test. Blood is drawn for the determination of PRA before and 4 hours after furosemide administration.

Interpretation Responses must be defined for the assay technique used. Patients with renin-dependent forms of hypertension (e.g., renovascular hypertension) show values that are approximately five times normal. Stimulated responses are also seen in patients with high-renin essential hypertension, pheochromocytoma, and Bartter's syndrome. Patients with hypertension from mineralocorticoid excess (e.g., primary aldosteronism) usually have PRA below the concentration of assay sensitivity. Patients with hyporeninemic hypoaldosteronism usually have low concentrations of plasma renin and low aldosterone concentrations. Figure 51-17 shows typical responses.

Another simple and convenient stimulation test consists of sodium restriction and upright posture. A low-salt diet containing less than 20 mmol/day of sodium is administered for 3 to 5 days; urine is collected for creatinine and sodium measurements until equilibrium with the new diet is established. At that point, a plasma renin activity is obtained after 2 hours of standing. A normal response is a twofold to threefold increase in plasma renin output.

Suppression Tests

Mineralocorticoid suppression tests have been designed that are based on salt loading.[31] For example, saline infusions, oral salt loading, or mineralocorticoid administration have been used to suppress the secretion of aldosterone by the adrenal gland. In normal individuals, acute expansion of the plasma volume with salt increases renal perfusion, suppresses renin release, and decreases aldosterone secretion. In the *saline suppression test,* isotonic saline is infused intravenously for 4 hours, after which plasma aldosterone concentration and renin activity are measured.[4,6] Aldosterone concentrations normally fall to <5 ng/dL (<140 pmol/L), and PRA is suppressed (Box 51-10). This test should not be performed if hypertension is severe or if cardiac failure is present. Administration of fludrocortisone, a synthetic mineralocorticoid, produces a comparable suppression of aldosterone secretion (see *fludrocortisone suppression test;* Box 51-11). Fludrocortisone should be administered with caution in patients with hypokalemia and heart or renal failure. An alternate suppression test uses the ACE inhibitor *captopril.*[95] This test is recommended when risks from volume overload preclude the use of other procedures. Captopril essentially inhibits the conversion of angiotensin I to angiotensin II, removing the angiotensin II stimulus to aldosterone secretion. Plasma aldosterone is measured, while the patient is sitting, before and 2 to 3 hours after the oral administration of 25 mg of captopril. Healthy subjects suppress plasma aldosterone to <15 ng/dL (410 pmol/L).

BOX 51-10 Protocol for the Saline Suppression Test

Rationale Rapid volume expansion with intravenous saline should suppress plasma aldosterone in normal subjects but not in patients with primary aldosteronism.

Procedure Care must be taken to ensure that the subject is not hypokalemic before starting the test. The subject is awakened at 0600 hours and kept in an upright posture for 2 hours. Blood is drawn for determination of plasma aldosterone at 0800 hours. The subject then assumes a supine position, and 2 L of isotonic saline, 0.9 g/dL, is infused over a 4-hour period. Blood is drawn for plasma aldosterone determination at noon.

Interpretation Normal subjects show a plasma aldosterone concentration of 5 ng/dL (140 pmol/L) or less after saline infusion. Concentrations >10 ng/dL are usually seen in patients with autonomously functioning aldosterone-secreting tumors.

Adrenal Androgen Function

Stimulation Tests

The responses of adrenal androgen secretion to ACTH stimulation are variable. Plasma DHEA and androstenedione increase threefold to fourfold after 90 minutes of stimulation with ACTH (10 μg/m^2). DHEA-S, on the other hand, increases 30% to 50% with ACTH administration. ACTH stimulation studies are not considered useful in evaluating hypoandrogenic disorders.[141]

Suppression Tests

Overnight suppression using dexamethasone produces small changes in adrenal androgen concentrations compared with those of cortisol. Dexamethasone, 0.75 mg, administered at midnight for several days reliably suppresses adrenal androgen concentrations measured in blood. Tissue stores of these androgens may account in part for the delay in the response.[106,135]

DISORDERS OF THE ADRENAL CORTEX

Thomas Addison first reported on hypofunction of the adrenal cortex in 1855.[124] However, it has only been in the last 60 years that many of the disease states that are associated with abnormal adrenal function have been discovered and studied. In general, diseases of this organ are classified as resulting from either hypofunction or hyperfunction of the adrenal cortex.

HYPOFUNCTION OF THE ADRENAL CORTEX

Adrenal Insufficiency[74,92]

Adrenal insufficiency is a rare disorder with a prevalence of only 4 to 11 cases per 100,000 population; if untreated it is fatal. The disorder is classified as primary,[195] secondary, or tertiary. *Primary adrenal insufficiency,* also known as

BOX 51-11 Protocol for the Fludrocortisone Suppression Test

Rationale Fludrocortisone, a potent mineralocorticoid, suppresses aldosterone production in normal subjects but not in subjects with primary aldosteronism.

Procedure Hypokalemia must be corrected before starting this test and serum potassium monitored during the test. Fludrocortisone, 0.1 mg every 6 hours, is given for 3 days. Plasma is collected for aldosterone determination after a standing position has been maintained for 2 hours (for baseline measurement) and at the end of fludrocortisone administration. Twenty-four-hour urine collections for measurement of aldosterone are obtained 1 day before fludrocortisone administration is started and on day 3 of the test course.

Interpretation Normal subjects show suppression of plasma aldosterone to <4 ng/dL (111 pmol/L); urine aldosterone is ≤20 μg/day on day 3.

Addison's disease, results from progressive destruction or dysfunction of the adrenal glands by a local disease process or systemic disorder (Box 51-12). Worldwide, infectious diseases are the most common cause of primary adrenal insufficiency and include tuberculosis, fungal infections (histoplasmosis and cryptococcosis), and cytomegalovirus infections. Autoimmune adrenalitis accounts for more than 70% of cases reported in the Western world, with adrenal autoantibodies noted in more than 75% of cases. The adrenal glands are atrophic, with loss of cortical cells but an intact medulla. Almost 50% of patients with autoimmune adrenalitis have an associated autoimmune disease with autoimmune thyroid disease the most common.

Because the entire cortex is affected in primary adrenal insufficiency, all classes of adrenal steroids are deficient.[135] The onset of clinical manifestations is usually gradual, and the degree and severity of symptoms depend on the extent of adrenal failure. In early or mild expressions of primary adrenal insufficiency, hypofunction may not be evident unless the patient is under stress. Complete glucocorticoid deficiency can manifest in a variety of ways, including fatigue, weakness, weight loss, gastrointestinal disturbances, and postprandial hypoglycemia. Mineralocorticoid deficiency leads to dehydration with hypotension, hyponatremia, and hyperkalemia. Excessive pituitary release of ACTH and related precursor peptides, unchecked by the negative feedback system, may cause hyperpigmentation of the skin and mucous membranes through the action of melanocyte-stimulating hormone on melanocytes.

BOX 51-12 Causes of Primary Adrenal Insufficiency

Autoimmune disease
- Sporadic
- Polyglandular autoimmune syndrome type I (Addison's disease, candidiasis, hypoparathyroidism, and primary gonadal failure)
- Polyglandular autoimmune syndrome type II (Addison's disease, primary hypothyroidism, primary hypogonadism, diabetes, and pernicious anemia)

Granulomatous disease
- Tuberculosis, histoplasmosis, sarcoidosis, fungal infections, and cytomegalovirus

Neoplastic infiltration
- Amyloid
- Hemochromatosis

Adrenoleukodystrophies
Congenital adrenal hypoplasia
ACTH resistance syndromes
HIV
Abdominal irradiation
Bilateral adrenalectomy
Intraadrenal hemorrhage: infection (caused by meningococci, *Pseudomonas*)
Anticoagulants

Measurement of basal ACTH and cortisol concentrations along with the ACTH stimulation test (see Box 51-1) is recommended if primary adrenal insufficiency is suspected from the patients' clinical history and symptoms. Basal plasma ACTH concentrations >150 pg/mL with serum cortisol concentrations <10 μg/dL are diagnostic of adrenal insufficiency (Figure 51-12). A subnormal cortisol response in the ACTH stimulation test supports the diagnosis of primary adrenal insufficiency (Figure 51-13). A normal cortisol response to ACTH stimulation establishes that the adrenal cortex is capable of releasing cortisol in a normal fashion. A subnormal response to ACTH stimulation suggests the diagnosis of secondary or tertiary adrenal failure.

In *secondary* and *tertiary adrenal insufficiency* (Table 51-5), inadequate cortisol production may be due to destructive processes in the hypothalamic-pituitary that result in a decreased ability to secrete ACTH (secondary) or CRH (tertiary).[135,169] However, the most common cause of tertiary insufficiency is chronic pharmacological administration of glucocorticoids that suppress CRH synthesis. This leads to a decrease in both ACTH release and cortisol secre-

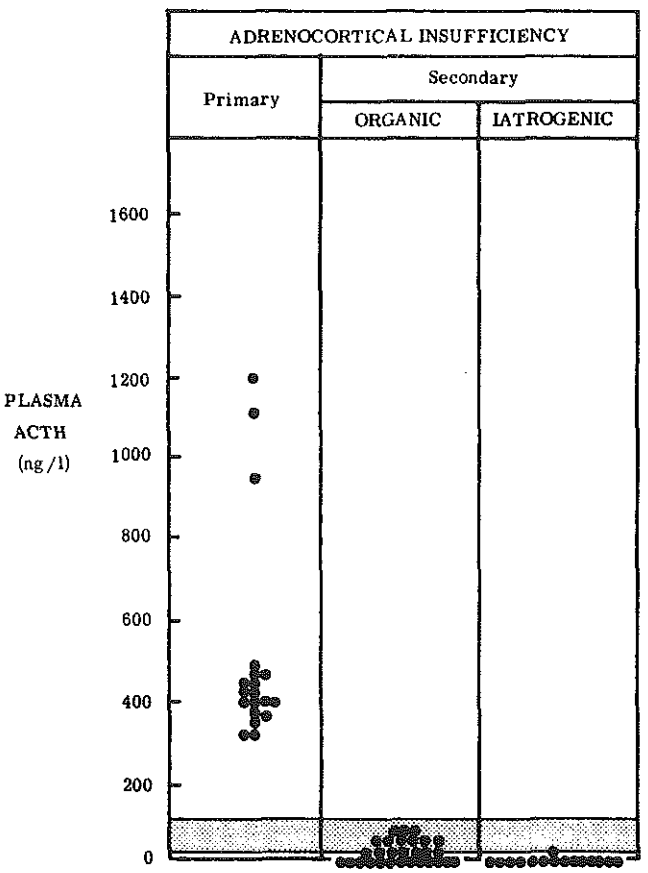

Figure 51-12 Basal plasma ACTH concentrations in primary and secondary adrenocortical insufficiency. *(From Irvine WJ, Toft AD, Feek CM. Addison's disease. In: James VHT, ed. The adrenal gland. New York: Raven Press, 1979:131.)*

tion. The clinical features of secondary and tertiary adrenal insufficiency are similar to those of primary insufficiency, except that hyperpigmentation is not present and hypotension is less severe; mineralocorticoid deficiency and ACTH excess are not seen in secondary or tertiary adrenal insufficiency. The ACTH stimulation test is also used to determine adrenal insufficiency in patients with secondary and tertiary adrenal insufficiency. When results are abnormal, however, the ACTH stimulation test cannot identify the cause of adrenal failure. Mild to moderate dysfunction of ACTH secretion may go undetected. Some patients with partial ACTH deficiency maintain sufficient ACTH to prevent adrenal atrophy, but are unable to augment ACTH secretion in response to stress or hypoglycemia.[135,169] In these cases, pituitary ACTH reserve can be investigated with either a metyrapone (see Box 51-4) or insulin-induced hypoglycemia test (see Box 50-3; Chapter 50). Neither test, however, should be performed if primary adrenal insufficiency is suspected. Subnormal responses to these tests suggest that pituitary ACTH release is inadequate, thus supporting a diagnosis of secondary or tertiary adrenal insufficiency. Basal ACTH and cortisol concentrations are often not useful for establishing the diagnosis of secondary adrenal insufficiency. Episodic secretion and circadian variation of both ACTH and cortisol can result in values in normal subjects that overlap with those with secondary or tertiary adrenal insufficiency. An elevated basal plasma ACTH in a patient with an abnormal response to acute ACTH stimulation suggests primary adrenal failure, whereas a low ACTH value and subnormal response to the Synacthen stimulation test suggest a hypothalamic or pituitary disorder.

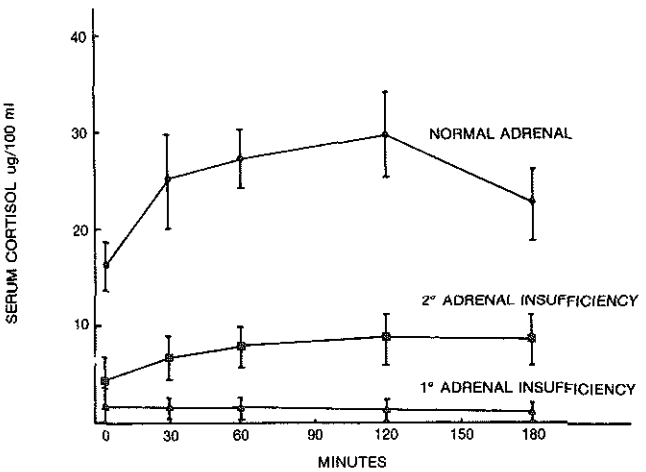

Figure 51-13 Serum cortisol response to 0.25 mg of cosyntropin (ACTH) in nine normal individuals (normal adrenal), eight patients with hypopituitarism (secondary adrenal insufficiency), and seven patients with Addison's disease (primary adrenal insufficiency). *(From Spechart P, Nicoloff J, Bethune J. Screening for adrenocortical insufficiency with cosyntropin [synthetic ACTH]. Arch Intern Med 1971;128:761. Copyright 1971, American Medical Association.)*

The multiple-day ACTH stimulation test is used to distinguish between primary and secondary or tertiary causes of adrenal insufficiency (see Box 51-2). It is particularly useful when patients have been receiving glucocorticoid therapy. In primary adrenal insufficiency, the damaged adrenal glands do not respond even with several days of repeated ACTH stimulation. Patients with secondary or tertiary adrenal insufficiency usually have an inadequate or absent cortisol response at first because the adrenal glands have been unstimulated for some time and steroidogenesis needs priming. Eventually, a delayed or staircase response is seen, indicating reactivation of the normal steroidogenic

TABLE 51-5 Adrenocortical Insufficiency

		Adrenal Insufficiency		
	Normal	**Primary**	**Secondary**	**Tertiary**
Screening Tests				
Plasma ACTH (0800 hours)	10-85 pg/mL	Increased	Normal or decreased	Normal or decreased

TABLE 51-6 Syndromes of Hypoaldosteronism

Entity	Mechanisms	Comments
Addison's disease	Diffuse destruction of adrenal cortex including the zona glomerulosa	
Heparin treatment	Direct effect of heparin therapy	Usually after prolonged treatment
After resection of aldosterone-producing adenoma	Suppression of aldosterone secretion in normal cortical tissue by adenoma with delayed recovery after surgery	Can be prevented by spironolactone treatment before surgery
Hyperreninemic hypoaldosteronism	Selective injury to the renal zona glomerulosa during hypotensive episodes in critically ill patients	Cortisol secretion is intact; presents with hyperkalemia in intensive care unit patients
Congenital adrenal hyperplasia with methyloxidase type II defect	Enzymatic block in the conversion of 18-OHβ corticosterone to aldosterone	
Pseudohypoaldosteronism	Decreased responsiveness to aldosterone caused by mineralocorticoid receptor defect	Aldosterone concentrations are higher
Hyporeninemic hypoaldosteronism	Low renin secondarily decreasing aldosterone secretion	Seen in diabetic and older patients with mild renal failure

pathways. This test, however, is not used as frequently in this situation because of the availability of better and sensitive ACTH immunoassays that more accurately determine ACTH concentrations at baseline. In primary adrenal insufficiency, the ACTH concentration is disproportionately elevated compared with the plasma cortisol concentration.

The CRH stimulation test (see Box 51-3) can be used to differentiate tertiary from secondary adrenal insufficiency.[131] Those with tertiary disease show an elevation in ACTH with CRH administration, whereas those with secondary disease show only minimal changes in ACTH concentrations.

Although subnormal basal plasma concentrations of DHEA-S occur in primary, secondary, and tertiary forms of adrenal insufficiency, measurement is of little value in the diagnosis of adrenal insufficiency; low concentrations of adrenal androgens are normally observed in children and in the elderly. Patients with human immunodeficiency virus (HIV) infection have been shown to have reduced concentrations of DHEA-S.[108] DHEA-S concentrations are usually determined in the management of women with hirsutism or in patients suspected of having adrenal tumors.[202]

Measurement of adrenal autoantibodies has been shown to be useful in evaluating patients suspected of adrenal insufficiency. Antibodies against the 21-hydroxylase enzyme have been used in this regard.

Hypoaldosteronism

Deficient aldosterone production occurs in conditions other than Addison's disease (Table 51-6).[6] Isolated aldosterone deficiency[190] accompanied by normal cortisol production is seen in patients with (1) inadequate production of renin by the kidney, which leads to secondary aldosterone deficiency (hyporeninemic hypoaldosteronism); (2) inherited enzyme defects in aldosterone biosynthesis; and (3) acquired forms of primary aldosterone deficiency (heparin therapy and postsurgery). The resulting metabolic changes are hyperkalemia and hyponatremia, often with a hypochloremic acidosis. Mild or moderate volume depletion, often with postural or unprovoked hypotension, may also occur. Hyporeninemic hypoaldosteronism can be established by demonstrating failure of both plasma renin and aldosterone to increase in response to furosemide stimulation or upright posture (see Box 51-9).[6] This disorder is more common in older patients and in individuals with diabetes mellitus. A high-renin form has been observed less frequently than the hyporenin form.

Patients with primary adrenal insufficiency usually also have aldosterone deficiency. Most endocrinologists, however, do not conduct tests to confirm aldosterone deficiency in these patients.

Hyperfunction of the Adrenal Cortex

Hyperfunction of the adrenal cortex produces clinical syndromes of glucocorticoid excess, mineralocorticoid excess, and androgen excess.[99,111,135]

Corticosteroid Excess (Cushing's Syndrome)[16,128]

In 1912 Harvey Cushing first described a 23-year-old woman with hirsutism, obesity, and amenorrhea and called it a polyglandular syndrome with pituitary involvement. Cushing's syndrome is the result of autonomous, excessive production of cortisol leading to classic symptoms characteristic of this disorder.[135,169] The clinical picture includes truncal obesity, moon face, hypertension, hirsutism,

ACTH, Adrenocorticotropic hormone.

hypokalemic metabolic alkalosis, carbohydrate intolerance, disturbance of reproductive function, and neuropsychiatric symptoms (Table 51-7). Frequently the cause is iatrogenic, caused by excessive exogenous steroid therapy. Endogenous disorders that cause hypersecretion of cortisol and Cushing's syndrome are classified either as *ACTH dependent* or *ACTH independent* (Table 51-8). Cushing's disease is the pituitary-dependent form of Cushing's syndrome that accounts for 70% of the cases seen in clinical practice. In Cushing's disease, hypersecretion of ACTH by a pituitary microadenoma is the primary defect that leads to bilateral adrenal hyperplasia and cortisol overproduction. In the ectopic ACTH syndrome, nonendocrine tumors (e.g., lung, gut, ovarian, and carcinoid tumors) develop the ability to secrete ACTH, resulting in adrenal hyperplasia, unregulated cortisol secretion, and suppression of pituitary ACTH activity. In the form of Cushing's syndrome associated with primary adrenal disease, such as adrenocortical adenoma[85] or carcinoma (see Table 51-8), increased secretion of cortisol suppresses both CRH synthesis and ACTH secretion, and atrophy of nontumorous adrenal tissue results. Multiple endocrine neoplasia type 1 (MEN 1) and type 2 (MEN 2) also are causes of Cushing's syndrome. MEN 1 results in Cushing's syndrome through ACTH hypersecretion from a pituitary microadenoma or from an ectopic ACTH-secreting tumor of the pancreas or medullary thyroid.

Screening Tests for Cushing's Syndrome

Cushing's syndrome is an uncommon disorder but many of the usual signs and symptoms of this syndrome are seen in patients with normal adrenal function. The initial diagnosis of Cushing's syndrome, particularly in mild or early disease, rests on laboratory evidence of excessive and autonomous cortisol production.[135,144,169] Two simple screening tests are available for detecting Cushing's syndrome (Table 51-9). One is the measurement of 24-hour urinary free cortisol. Under normal circumstances, <2% of the secreted cortisol appears in urine as free cortisol. In general, a 24-hour urinary free cortisol concentration <100 μg/day excludes the diagnosis of Cushing's syndrome, and concentrations >120 μg/day suggest the diagnosis of Cushing's syndrome (see Figure 51-9). The diagnostic accuracy is more than 90% when the test is properly performed.[17] An elevated excretion rate documents overproduction of cortisol. However, improper timing of the urine specimen (>24 hours), concomitant use of a diuretic, high salt intake, depression, and stress can cause false-positive test results.[135] Urine cortisol measurements do not establish the diagnosis; an abnormal result should be followed by repeat or provocative testing.

Another reliable and convenient screening test for Cushing's syndrome is the overnight low-dose dexamethasone suppression test (1 mg at midnight) with measurement of serum cortisol (suppressed to <5 μg/dL [140 nmol/L]) at 0800 hours the following morning (see Box 51-5). A multiple low-dose test is sometimes also used (see Box 51-6). A diagnostic accuracy of 90% has been achieved with the simultaneous measurement of both cortisol and dexamethasone, although this approach is rarely used.[17,135] The measurement of dexamethasone assesses the resistance of the HPA axis to suppression. Incorrect dosing and alterations in clearance of dexamethasone are detected by measuring dexamethasone; thus both false-negative and false-positive suppression test results can be identified.

Examining the circadian rhythm of cortisol secretion can also be used to screen for Cushing's syndrome. The morning to night difference is lost in patients with Cushing's syndrome so that the nocturnal concentrations are inappropriately raised from normal.

Differential Diagnosis of Cushing's Syndrome

The screening tests discussed above suggest endogenous Cushing's syndrome. More definitive testing should then be

TABLE 51-9 Differential Diagnosis in Cushing's Syndrome

	Normal	Cushing's Syndrome	Adrenal Tumor	Ectopic ACTH Syndrome
Screening Tests				
Urinary free cortisol	<100 μg/day	>120 μg/day	>120 μg/day	>120 μg/day
Overnight dexamethasone suppression test (see Box 51-5)				
Serum cortisol (0800h)	<3 μg/dL	>10 μg/dL	>10 μg/dL	>10 μg/dL
Differential Diagnostic Tests				
Plasma ACTH (0800 h)	10-85 pg/mL	40-260 pg/mL	<10 pg/mL	Normal to greatly elevated
Serum cortisol (0800 h)	5-23 μg/dL	Normal	Normal or elevated	Normal or elevated
High-dose overnight dexamethasone suppression test (see Box 51-8)				
Serum cortisol (0800 h)	50% suppression	Most suppress	Fail to suppress	Fail to suppress

performed to determine the source of the overproduction of cortisol when observed with screening tests (see Table 51-9). Plasma ACTH concentrations are low in patients with adrenal tumors and normal or moderately elevated in patients with Cushing's syndrome and macronodular hyperplasia. The plasma concentrations of ACTH are very often markedly elevated in patients with nonendocrine ACTH-secreting tumors (Figure 51-14) because the normal negative feedback loop does not respond in this situation. Plasma ACTH concentrations >300 pg/mL are usually suggestive of a nonendocrine ACTH-secreting tumor.

High-dose dexamethasone suppression testing (see Boxes 51-7 and 51-8) is useful to differentiate Cushing's syndrome caused by adrenal tumors and nonendocrine ACTH-secreting tumors from pituitary Cushing's disease.[135,169] Some patients with Cushing's disease have false-negative test results with low-dose dexamethasone suppression. False-negative test results can be assessed by administering either 1.0 mg (low dose) or 8 mg (high dose) of dexamethasone at midnight (overnight dexamethasone suppression test). Serum is collected at 0800 hours for the measurement of cortisol. In patients with adrenal tumors and, with a few exceptions, in those patients with nonendocrine ACTH-secreting tumors, suppression does not occur after high-dose dexamethasone administration. Most patients with macronodular hyperplasia do not show normal suppression on high-dose testing with either the overnight or multiple-dose tests. They usually have measurable concentrations of ACTH. With high-dose testing, <10% of patients with Cushing's disease fail to show some degree of suppression, although most show only 50% to 60% suppression.[17] False-positive results have occurred in patients with accelerated clearance of dexamethasone as in patients receiving hepatic enzyme–inducing drugs, such as phenytoin. In these patients, measurements of plasma dexamethasone can be useful to gauge the effective blood concentration.

The CRH stimulation test (see Box 51-3) produces exaggerated ACTH or cortisol responses, or both, in about 90% of patients with Cushing's disease.[93,135,169] Poor responses occur in patients with adrenal tumors and in most patients with nonendocrine ACTH-secreting tumors (usually those having elevated basal concentrations of plasma ACTH). Patients with depression and anorexia nervosa usually do not exhibit exaggerated responses of ACTH to CRH injections. CRH testing has no major advantage over the high-dose dexamethasone suppression test. If the cause of Cushing's syn-

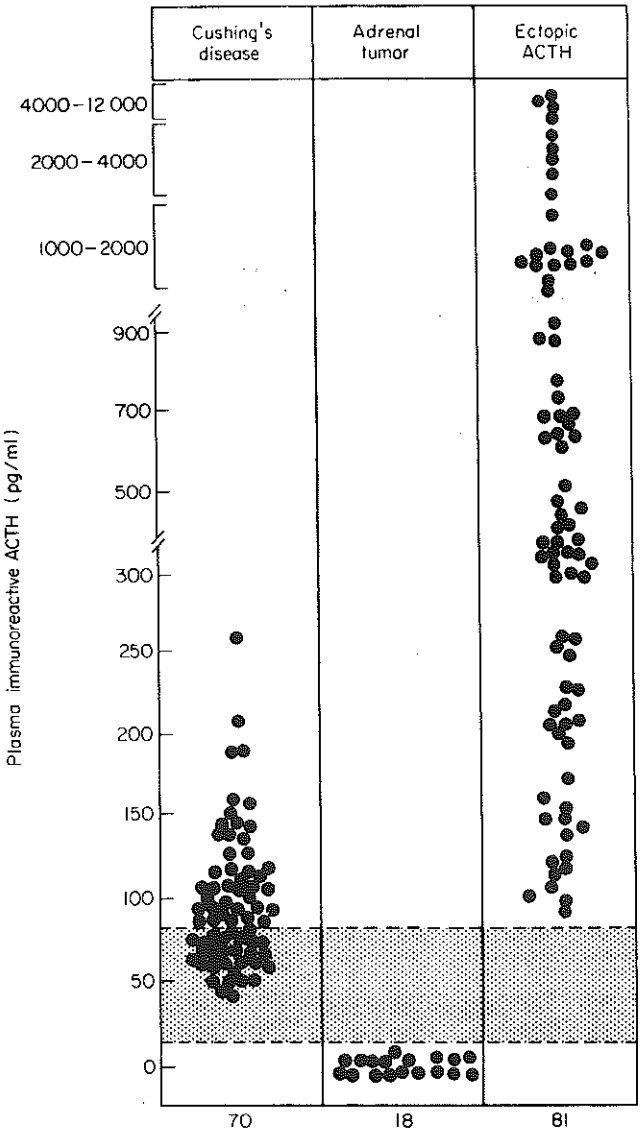

Figure 51-14 Basal plasma ACTH concentrations in patients with spontaneous Cushing's syndrome. *(From Scott AP. Pituitary adrenocorticotrophin and the melanocyte stimulating hormones. In: Parsons JA, ed. Peptide hormones. Baltimore: University Park Press, 1979.)*

drome is uncertain, measurement of ACTH from inferior petrosal vein specimens before and after CRH stimulation can be helpful. When ACTH concentrations in petrosal vein specimens are similar to those of simultaneously obtained peripheral vein plasma specimens, the diagnosis of a nonpituitary source of the ACTH is then considered. In virtually all patients with ectopic production of ACTH, the ratio of ACTH concentrations between the IPS and a peripheral venous concentration is <1.4:1. In contrast patients with Cushing's disease have a ratio >3.0. Unilateral elevation of petrosal vein ACTH, however, does not always predict which side of the pituitary the tumor is hypersecreting ACTH.[131]

BOX 51-13 Tests for Anatomical Localization of Defects in Cushing's Syndrome

Pituitary Studies
CT; MRI; selective venous sampling for ACTH measurements (inferior petrosal sinus venous to peripheral venous ratios)

Adrenal Studies
CT; selective arteriography; selective venography; selective venous sampling for cortisol measurement

Ectopic ACTH Production
Conventional radiography, ultrasonography, CT to look at sites of suspected neoplasms

ACTH, Adrenocorticotropic hormone; *CT,* computed tomography; *MRI,* magnetic resonance imaging.

Adrenal androgens and plasma DHEA-S are measured in the differential diagnosis of hirsutism without Cushing's syndrome.[37,135] In patients with Cushing's syndrome, plasma DHEA-S concentrations are usually normal or moderately elevated (plasma DHEA-S ~5 μg/mL). Those patients with an adrenal adenoma usually have low age-adjusted concentrations of DHEA-S. The concentrations for plasma DHEA-S in patients with nonendocrine ACTH-secreting tumors range from normal to elevated. In patients with congenital adrenal hyperplasia (CAH), adrenal androgens suppress normally with the administration of 0.75 mg of dexamethasone for 2 to 3 weeks, but suppression does not occur in those patients with adrenal tumors and nonendocrine ACTH-secreting tumors.

In addition to suppression and stimulation testing, methods of anatomical localization, listed in Box 51-13, should be used to document the diagnosis of Cushing's syndrome. Computed tomography (CT) of the adrenal glands has been helpful in localizing adrenal tumors, macronodular hyperplasia, and bilateral hyperplasia of the adrenal glands. CT in combination with magnetic resonance imaging (MRI) of the pituitary gland can help detect pituitary microadenomas.[24,135]

Conditions That Mimic Cushing's Syndrome

Alcohol abuse has been known to induce a "pseudo-Cushing's syndrome" that mimics the clinical and biochemical features of the actual disease.[135,169] The abnormalities are all reversible once alcohol abuse by the patient is eliminated. The clinician must therefore use considerable judgment in detecting the cause of Cushing's syndrome before therapy.[35,194] HIV, anorexia nervosa, and depression are associated with elevated serum cortisol concentrations, and patients with these disorders may have positive low-dose, overnight dexamethasone suppression tests. However, the clinical features of patients with HIV and anorexia nervosa are not typical of those with Cushing's syndrome. Measurement of urinary free cortisol and plasma cortisol with the dexamethasone suppression test improves the predictive value in the diagnosis of both Cushing's syndrome and depression.[107]

Obese patients have also presented with clinical features that mimic true Cushing's syndrome. Truncal obesity, striae, and the excretion of elevated concentrations of 17-hydroxysteroids are features of Cushing's syndrome that occur in normal, obese subjects. Urinary free cortisol, however, is normal in the obese individual and can effectively differentiate normal subjects from those with true Cushing's syndrome.

Congenital Adrenal Hyperplasia (Adrenogenital Syndrome)[126]

The biosynthesis of cortisol and aldosterone from cholesterol requires the action of specific enzymes in the adrenal cortex for the chemical modification and introduction of the different functional groups.[112,176,199,200] CAH is characterized by the congenital absence or deficiency of one or more of the biosynthetic enzymes that lead to cortisol biosynthesis.[113] As noted in Figure 51-6, a defect or deficiency in any one or all of the four key enzymes of adrenocorticoid biosynthesis can occur. As a result, cortisol biosynthesis is impaired, leading to a compensatory increase in ACTH release. ACTH then stimulates steroid biosynthesis to the point of the enzyme block. Enzyme defects therefore cause hyperplasia of the adrenal cortex and accumulation of intermediate compounds proximal to the block with shunting of the substrate toward the adrenal androgen pathway. Measurements of the specific precursor steroids in blood are useful for identifying the specific enzyme defect and for monitoring response to cortisol replacement therapy.[199,200]A partial block may cause either marked or subtle clinical manifestations, whereas a complete enzyme block can be incompatible with life. The closer the enzyme block is to the final cortisol product, the less life threatening are the symptoms caused by compensatory action by the elevated precursor steroids.

The term CAH is used to denote the congenital presentation of this disorder (usually at birth) and the adrenocortical hyperplasia that results from the compensatory ACTH response to cortisol deficiency. "Adrenogenital syndrome" is also used to describe this disorder in that it affects the genitalia and secondary sex characteristics of the newborn. In girls, particularly, the diagnosis of CAH in the neonatal period is commonly suggested first by the observed presence of ambiguous genitalia. In boys the abnormality may not be suspected until signs of precocious puberty or accelerated growth are present. Because aldosterone production can be compromised with accumulation and diversion of intermediate steroids to other pathways, hypertension and salt wasting may also be present. The adrenogenital syndrome is recognized with increased frequency in adults, with affected people presenting with subtle abnormalities at the time of puberty that go unrecognized. In adult women, the clinical presentation may be indistinguishable from the polycystic ovary syndrome (PCOS) or idiopathic hirsutism.[8,213]

Deficiency of the 21-hydroxylase enzyme (Figure 51-15; see also Figure 51-6) is the most common form of CAH, with more than 90% of cases caused by 21-hydroxylase deficiency.[199,200] The incidence in Western societies ranges from 1 in 5000 to 1 in 15,000 live births. An elevation in 17α-hydroxyprogesterone is characteristic of this enzyme defect. The concentrations of several other steroids are increased in the circulation of patients with 21-hydroxylase deficiency. These include progesterone, 17α-hydroxypregnenolone, and pregnenolone. The adrenal androgens, DHEA-S and DHEA, are also elevated in patients with this enzyme defect. An increase in plasma androstenedione and testosterone occurs primarily as a result of the peripheral conversion of precursor adrenal androgens by the liver. There are several variants of 21-hydroxylase deficiency: a simple virilizing form, a salt-wasting form, and a late-onset form. The simple virilizing form is associated with 21-hydroxylase enzyme deficiency occurring only in the zona fasciculata, and the major clinical manifestation is virilization caused by the increase in adrenal androgen secretion. The salt-wasting form extends

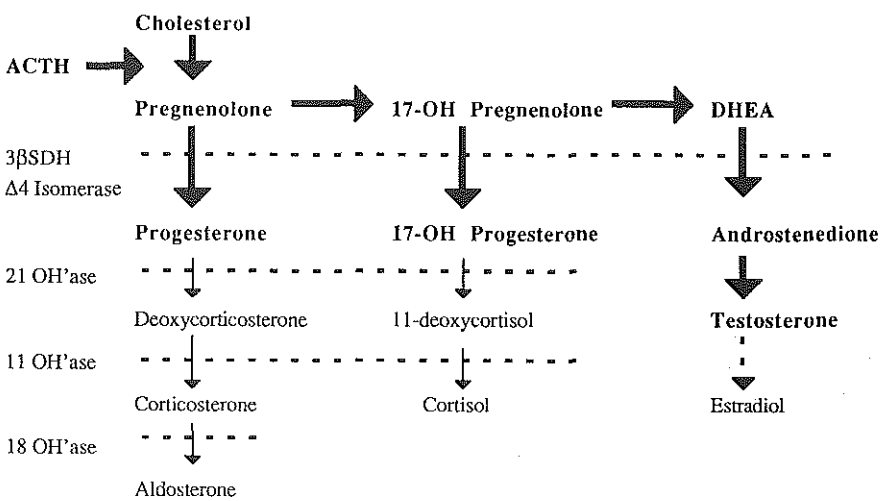

Figure 51-15 Formation of steroids in patients with adrenogenital syndrome caused by 21-hydroxylase deficiency. Bold lettering indicates steroids that are found elevated in the circulation. *ACTH,* Adrenocorticotropic hormone; *3βSDH,* 3β-hydroxysteroid dehydrogenase.

to the zona glomerulosa and includes a deficiency in aldosterone leading to salt wasting and hypotension. Late-onset 21-hydroxylase deficiency is associated with mild to moderate hirsutism in women in early adulthood that commonly masquerades as PCOS, with primary or secondary amenorrhea and anovulation as major characteristics. Plasma testosterone and androstenedione and basal and ACTH-stimulated 17α-hydroxyprogesterone concentrations are elevated in these individuals. Plasma 3α-androstanediol glucuronide, a metabolite of tissue androgens, is also elevated in most patients with this enzyme deficiency. Males can develop enlarged testes because of ectopic adrenal tissue that rests within the testes and responds to the ACTH compensatory increase. The ACTH stimulation test with the measurement of 17-hydroxyprogesterone (see Box 51-1) is useful in identifying heterozygotes for this condition and exposing patients with acquired forms of 21-hydroxylase deficiency.

A deficiency *of 11β-hydroxylase* is the second most common form of CAH, with an incidence of 1 per 100,000 births, and is associated with manifestations of virilization, elevated concentrations of plasma androstenedione and DHEA-S, and hypertension. The mineralocorticoid-induced hypertension is caused by an elevation of DOC; 11-deoxycortisol concentrations are markedly raised in subjects with this enzyme defect.[199,200] The major distinguishing characteristic of this disorder from 21-hydroxylase deficiency, besides the elevated plasma concentrations of 11-deoxycortisol, is hypertension elicited by the salt retention caused by increased concentrations of DOC. A deficiency of 3β-*hydroxysteroid dehydrogenase-isomerase* has been reported and leads to an elevation in the ratio of 17α-hydroxypregnenolone to that of 17α-hydroxyprogesterone and to an increased ratio of DHEA to androstenedione. In severe forms of this rare disorder, female infants have pseudohermaphroditism, and male infants present with incomplete masculinization. Patients with this disorder usually present in early infancy with complete adrenal insufficiency including salt wasting. A late-onset form has also been reported in patients with premature pubarche with hirsutism, acne, and menstrual irregularities.[13,138,199,200,213] The diagnosis is made by demonstrating an increased ratio of pregnenolone and 17-hydroxypregnenolone to progesterone and 17-hydroxyprogesterone, respectively.

A reduction in the conversion of 17-hydroxypregnenolone to DHEA and of 17-hydroxyprogesterone to androstenedione results from a deficiency of *C-17,20-lyase/17α-hydroxylase*. A defect of this enzyme complex in the gonads of genetic females results in pubertal failure, and a defect in genetic males causes pseudohermaphroditism. The synthesis of cortisol, androgens, and estrogens is decreased, and the production of progesterone, corticosterone, and DOC is increased. In the complete form, hypertension and hyperkalemia with a lack of sexual development are observed in girls, whereas male pseudohermaphroditism is seen in boys. The diagnosis is usually made at the time of puberty when patients present with hypogonadism in association with hypertension and hypokalemia.

Concentrations of all classes of steroid hormones are low when a deficiency of the cholesterol side-chain cleavage enzyme is present. This disorder is extremely rare; few affected children survive infancy, and sexual differentiation is absent in boys.

The effectiveness of a treatment program for CAH is judged on the basis of the presence or absence of normal linear growth, normal sexual development, and suppression of abnormal blood and urine steroid concentrations into the normal range with exogenous cortisol. With virilizing congenital hyperplasia caused by either 21-hydroxylase deficiency or 11α-hydroxylase deficiency, excess DHEA and androstenedione from the adrenal glands is converted to testosterone in peripheral tissue; plasma testosterone values within the reference interval of the adult male are commonly encountered in infants diagnosed with CAH. With effective treatment, suppression of plasma testosterone to <0.2 ng/mL is achieved. Most pediatric endocrinologists use cortisol replacement therapy in these patients with measurement of the elevated steroid just proximal to the enzyme block and with androstenedione concentrations. Increases in androstenedione are an early indicator of inadequate steroid replacement.

Adrenal Tumors[171]

Plasma DHEA-S, DHEA, androstenedione, and testosterone concentrations are elevated in patients with virilizing adrenal adenomas and Cushing's syndrome. The plasma concentrations of DHEA also may be elevated in women with virilizing ovarian tumors. CT scans along with MRI are useful in differentiating the sites of the tumors.[37,169] Aldosterone-secreting adenomas referred to as Conn's syndrome are typically small microadenomas found in the zona glomerulosa that hypersecrete aldosterone, producing the syndrome characterized by low renin hypertension.

Adrenal carcinomas are rare, with an incidence of only 1 per million population, and may cause only virilization and not the typical features of Cushing's syndrome. Women are more commonly affected than men in a 2.5:1 ratio. Plasma DHEA-S, DHEA, and androstenedione concentrations are markedly elevated in patients with adrenal carcinoma along with raised concentrations of cortisol. The concentrations of DHEA-S can often exceed 10 μg/mL in patients presenting with adrenal carcinoma and are usually diagnostic of this malignancy. High-dose glucocorticoids do not suppress the elevated androgen concentrations.[37,169]

Feminizing adrenocortical carcinomas are also rare.[37,169] They result in elevation of plasma DHEA-S, DHEA, androstenedione, estrone, and estradiol concentrations. Serum cortisol concentrations may be normal or elevated in those patients with Cushing's syndrome. Gynecomastia and sexual dysfunction occur in men and precocious pseudopuberty in women. Steroid hormone production fails to decrease normally after treatment with dexamethasone.

TABLE 51-10 Differential Diagnosis of Hyperaldosteronism

	Plasma Renin	Plasma Aldosterone	Blood Pressure	Serum Potassium
Primary aldosteronism	Low	High	High	Low
Secondary hypertension				
Edematous disorder	High	High	Normal	Low
Malignant hypertension	High	High	High	Low
Renovascular hypertension	Normal or high	Normal or high	High	Normal or low
Renin-secreting tumors	High	High	High	Normal or low
CAH (11- and 17-hydroxylase deficiency)	Low	Low	High	Low
Cushing's syndrome	Normal or low	Normal or low	High	Low
Liddle's syndrome	Low	Low	High	Low
Bartter's syndrome	High	High	Normal or low	Low
Licorice ingestion	Low	Low	High	Low
Low-renin essential hypertension	Low	Normal or low	High	Normal
Ingestion of exogenous mineralocorticoids	Low	Low	High	Low

CAH, Congenital adrenal hyperplasia.

Nonfunctioning Adrenocortical Tumors

Approximately 2% of the population have an adrenal tumor; most of these tumors are nonfunctioning and are sometimes called incidentalomas. They are found when CT scans of the abdomen are performed that can easily detect tumors 1 cm in diameter or 5 g in weight. No virilizing tumors smaller than 1 cm in diameter have been reported. Carcinomas are usually more than 30 g in weight.[37,169]

Mineralocorticoid Excess (Hyperaldosteronism)[28,133]

Hyperaldosteronism, commonly referred to as Conn's syndrome, is a syndrome associated with hypersecretion of the major mineralocorticoid, aldosterone.[6,64] In *primary aldosteronism,*[90,132,193,196] excessive aldosterone production originates from within the adrenal gland; in *secondary aldosteronism,* a stimulus outside the adrenal gland activates the renin-angiotensin system. The interaction of renin, angiotensin, and aldosterone is important in the regulation of extracellular fluid volume, blood pressure, and the balance of sodium and potassium ions. A change in one of these variables leads to changes in the others.

Control of renin release from the kidney is influenced by (1) specialized cells in the distal convoluted tubules called the macula densa function as chemoreceptors for the concentration of sodium delivered to the distal tubules; (2) juxtaglomerular cells functioning as mini pressure transducers sense the renal perfusion pressure in the kidney; (3) the sympathetic nervous system that feeds the kidney and catecholamine release; and (4) humoral factors such as potassium, atrial natriuretic peptides, and angiotensin II. All of these influences are involved in the normal control of salt and water balance and with diseases of the kidney. Secondary events that disturb the normal equilibrium of renin release are much more common than primary abnormalities of renin secretion (Table 51-10). For example, a decrease in effective plasma volume or mean arterial pressure with sudden blood loss leads to release of renin from juxtaglomerular cells of the kidneys; more angiotensin I and angiotensin II are formed, and an increased production of aldosterone by the adrenal glands occurs. This results in retention of water and sodium, an increase in extracellular volume, and a decrease in the serum potassium ion concentration. This state of secondary aldosteronism is commonly present in patients with congestive heart failure, nephrotic syndrome, cirrhosis of the liver, other hypoproteinemic states, or conditions of chronic depletion of plasma volume.

Secondary hyperaldosteronism is suspected in patients with volume depletion, edema, and hypokalemic alkalosis. Measurements of renin activities and aldosterone concentrations are seldom needed in these cases. Their measurements are invaluable, however, in the investigation of primary disturbances in the renin-angiotensin-aldosterone system, in the assessment of renal artery stenosis, and in the genesis and maintenance of arterial hypertension.

Primary Aldosteronism

Primary aldosteronism was first described by Conn in 1955 and is characterized by an elevated plasma concentration of aldosterone along with hypertension and hypokalemia.[4,6] Because <1% of hypertensive patients have primary aldosteronism, indications that should lead to further evaluation include hypokalemia that is unprovoked by diuretics or the lack of response to conventional antihypertensive drug treatment. Overproduction of aldosterone may be due to an

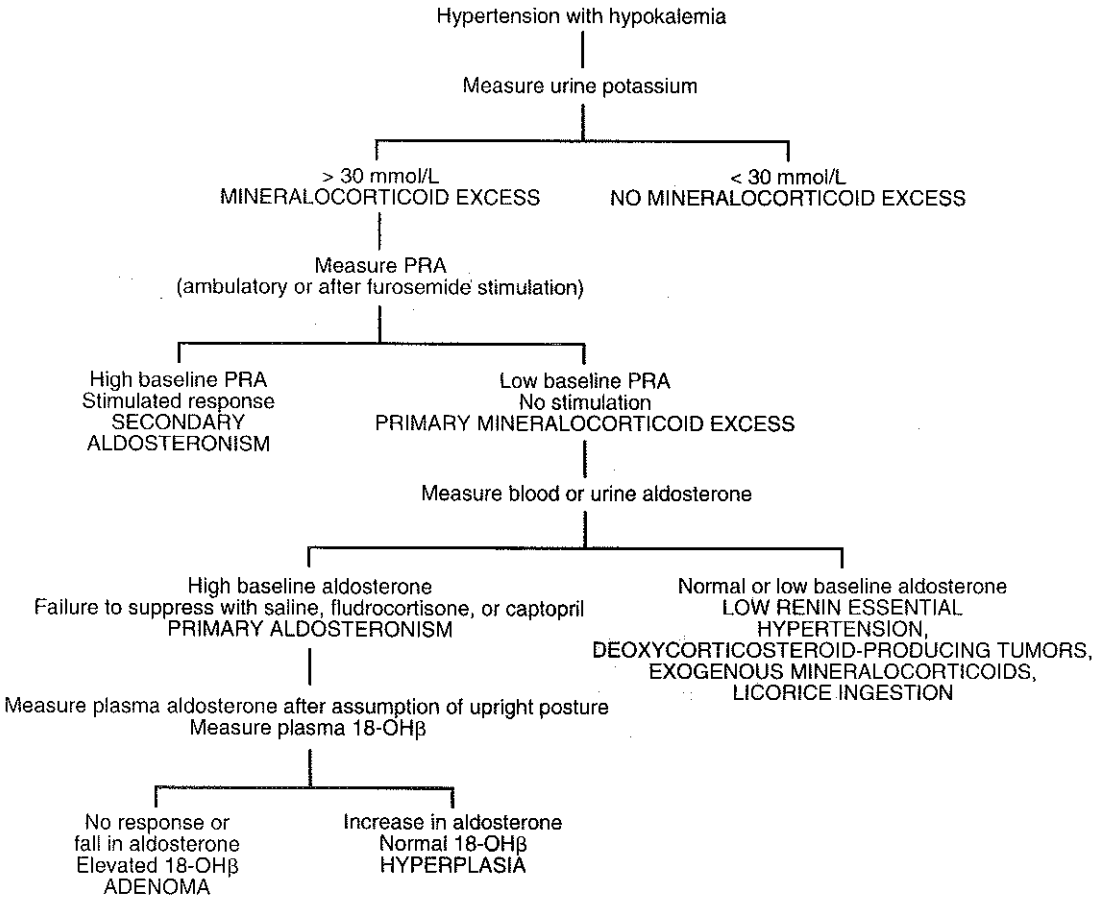

Figure 51-16 Scheme for the laboratory work-up of suspected aldosteronism causing hypertension. *PRA*, plasma renin activity; *18-OH*, 18-hydroxycorticosterone.

autonomous and inappropriate secretion of aldosterone by an adenoma of one adrenal gland (*aldosterone-producing adrenal adenoma* [APA] or *Conn's syndrome*), hyperplasia of aldosterone-producing cells in both glands (*idiopathic adrenal hyperplasia* [IAH]), an aldosterone-producing adrenal carcinoma, or a rare familial condition known as *glucocorticoid-suppressible aldosteronism.* The clinical features of primary aldosteronism are generally related to the consequences of aldosterone overproduction. Increased retention of sodium through the effects of aldosterone on the renal tubular handling of sodium, expansion of extracellular fluid volume, and increased tubular secretion of potassium and hydrogen ions reflect the cardinal manifestations of primary aldosteronism. Hypokalemia and metabolic alkalosis result as a consequence of a progressive renal depletion of body potassium. As a consequence of sodium retention, there is a modest expansion of extracellular fluid volume and an increase in arterial blood pressure.

Laboratory Diagnosis of Primary Aldosteronism

Hypokalemia is the key clinical finding that primary aldosteronism may be present in a patient with diastolic hypertension.[5] To confirm the diagnosis, it is necessary to demonstrate (1) hyposecretion of renin that is not appropriately corrected during volume depletion, and (2) hypersecretion of aldosterone that fails to suppress appropriately during volume expansion. Figure 51-16 shows a suggested scheme for evaluating patients with suspected mineralocorticoid excess.

Most patients with autonomous aldosterone overproduction are hypokalemic, but most patients with hypokalemia do not have primary aldosteronism. In hyperaldosteronism, urinary potassium excretion is inappropriately high, and a random urine potassium >30 mmol/L is usually indicative of primary aldosteronism or some type of mineralocorticoid excess condition. If hypokalemia can be shown to be due to nonrenal potassium loss, the diagnosis of aldosteronism does not need to be considered further.[4,6,64]

In primary aldosteronism, low renin activity and high aldosterone concentration are expected. Many other factors, however, influence the secretion of renin and aldosterone, and these factors must be recognized and understood before testing. Because drugs such as ACE inhibitors, beta blockers, and spironolactone alter renin release, patients should be withdrawn from these medications for several weeks before determining the plasma aldosterone/plasma renin activity

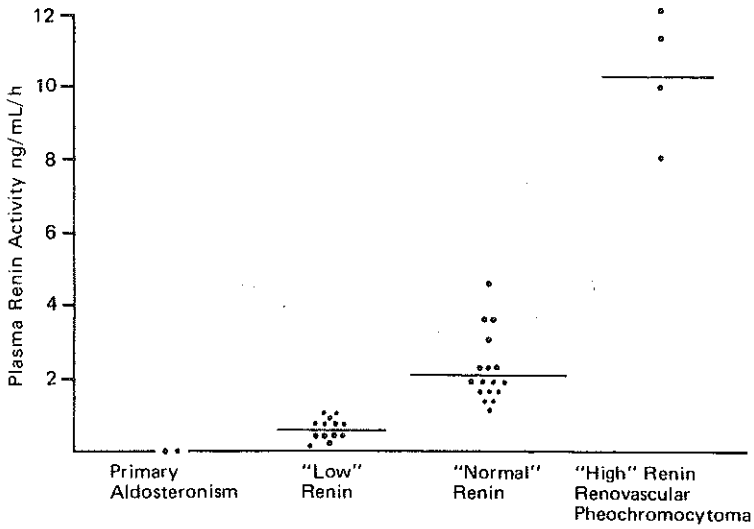

Figure 51-17 PRA 5 hours after the oral administration of 60 mg of furosemide. *(From Wallach L, Nyari I, Dawson K. Stimulated renin: A screening test for hypertension. Ann Intern Med 1975;82:27.)*

ratio. When working up patients with suspected primary aldosteronism, it is helpful, for example, to compare the ambulatory PRA activity with sodium excretion or to stimulate renin production with a potent diuretic such as furosemide (Figure 51-17). A high PRA activity could be due to secondary aldosteronism (e.g., renovascular hypertension or pheochromocytoma). A low value, on the other hand, suggests primary aldosteronism or low-renin hypertension. The latter may be caused by exogenous or endogenous mineralocorticoids that mimic the action of aldosterone, producing an expansion in plasma volume, hypertension, and hypokalemia. The use of an ACE inhibitor such as captopril has also been employed for the diagnosis of primary aldosteronism. In individuals who are normotensive or have essential hypertension, acute inhibition of ACE decreases angiotensin-mediated aldosterone production, and the autonomous aldosterone production from an aldosterone-producing adenoma is unaffected by the ACE inhibitor.

The determination of plasma renin responsiveness, however, is not sufficient to diagnose primary aldosteronism because suppressed PRA also occurs in about 25% of patients with essential hypertension. Primary aldosteronism can be differentiated from other hypermineralocorticoid states on the basis of inappropriate secretion of aldosterone. The demonstration of an elevated concentration of aldosterone in blood or urine in a patient with an unequivocally suppressed PRA concentration (a plasma aldosterone/plasma PRA ratio >50) is presumptive evidence of primary aldosteronism. Because hypokalemia has a suppressive effect on aldosterone secretion, the potassium deficit should be replaced before aldosterone measurements are done. To establish aldosterone autonomy, the clinician may attempt to suppress aldosterone production with rapid volume expansion[68] (see Box 51-10), with a potent mineralocorticoid (see Box 51-11),[5] or as mentioned with captopril. Failure of aldosterone to be suppressed using these maneuvers confirms a diagnosis of primary aldosteronism.

Once the diagnosis of primary aldosteronism is established, it is necessary to distinguish between APA and bilateral IAH. This differentiation is vital because most patients with adrenal adenomas respond well to surgical removal of the tumor, whereas patients with adrenal hyperplasia do not and are managed medically. Localization using imaging techniques[67] can be helpful (spiral CT scans,[3,52,165] ultrasonography, and adrenal scanning with NP-59 [^{131}I-6β-iodomethyl-19-norcholesterol]) and adrenal venography with or without selective adrenal venous sampling for aldosterone measurements to determine whether the right or left adrenal is hypersecreting aldosterone when the tumors are too small to be detected by imaging techniques. A number of biochemical clues can help with the differential diagnosis. Aldosterone hypersecretion and plasma renin suppression are usually greater with adrenal adenomas. After sodium depletion or after 2 to 4 hours of upright posture, patients with APA usually show no change or a paradoxical fall in plasma aldosterone, whereas patients with IAH typically show a rise in plasma aldosterone (presumably because the hyperplastic glands are sensitive to small increments in PRA).[48] Elevated plasma concentrations of aldosterone precursor substrates, such as 18-hydroxycorticosteroid (>85 ng/dL), are observed in most patients with APA but not in those with IAH (see Figure 51-16).

A small percentage of patients with APA or IAH respond to dexamethasone treatment with a normalization of their blood pressure and correction of their biochemical abnormalities.[39] Dexamethasone treatment should be attempted before surgery, particularly in young patients, or when the normal fall in plasma aldosterone concentration after salt depletion and standing does not occur, and no unilateral lesion is seen on radiographs. Also, a trial treatment of *spironolactone,* an aldosterone antagonist, usually normalizes

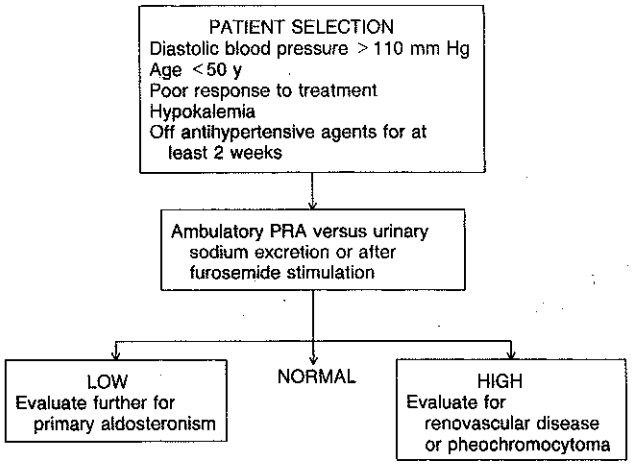

Figure 51-18 Screening with PRA in hypertension. *(From Watts NB, Keffer JH. Practical endocrine diagnosis, 3rd ed. Philadelphia: Lea & Febiger, 1982. Used with permission.)*

blood pressure in patients who are likely to have a good response to surgery.

Other Causes of Adrenal Mineralocorticoid Excess

Adrenocortical carcinomas have been found to produce excess mineralocorticoid and cause hypertension with hypokalemia.[6,37] Either aldosterone or DOC, or both, may be produced in excess. Mineralocorticoid concentrations do not respond to glucocorticoid therapy or alterations in salt status. CT scans are helpful; adrenal carcinomas are usually large tumors that weigh more than 30 g; aldosterone-secreting adenomas are usually much smaller. Finding low plasma renin activity and aldosterone concentration under circumstances that should cause an elevation (furosemide stimulation or upright posture) would support the diagnosis (see Figure 51-17).

Other unusual conditions that suggest aldosterone excess or deficiency but are not connected to the renin-angiotensin-aldosterone system[163] include *Liddle's syndrome* (pseudohyperaldosteronism),[86] which resembles primary aldosteronism clinically, but aldosterone production is low and hypertension is absent; and *Bartter's syndrome,*[201] which involves a prostaglandin-mediated renal potassium wasting and renal chloride handling defect, in which both aldosterone concentrations and renin activities are elevated. In renal tubular acidosis and pseudohypoaldosteronism, the clinical picture of hypoaldosteronism is seen concurrent with greater-than-normal concentrations of aldosterone.

Plasma Renin in Renovascular Hypertension

Used as a screening test, an elevated plasma renin activity after furosemide stimulation or when correlated with urinary sodium excretion[78] can suggest renal artery stenosis as the cause of the hypertension (Figure 51-18). If there is arteriographic evidence for renal artery stenosis, measurement of plasma renin in specimens obtained from selective renal vein catheterization can be helpful in predicting the response to surgical correction of the renal vascular lesion or nephrectomy. Lateralization of renin in the renal vein to the radiographically involved side, especially after sodium depletion, is also predictive of a good response to surgery in 90% of cases (Box 51-14).[104] Comparing renin activity in the renal artery with that in the renal vein can make a further distinction.[188]

BOX 51-14 Protocol for the Differential Renal Vein Renin Test

Rationale In renovascular hypertension, PRA is higher in the renal vein on the involved side.

Procedure The patient should be on a low-sodium, high-potassium diet and receiving a diuretic for 3 days before the procedure. Under fluoroscopic guidance, percutaneous catheterization is performed, and blood samples are obtained from both renal veins and the inferior vena cava for determination of PRA.

Interpretation Various criteria have been suggested for interpretation. A ratio of PRA (affected side to unaffected side) that is >1.5 suggests functionally significant renovascular disease.

ANALYTICAL METHODOLOGY

Many different types of methods have been used to measure steroids in body fluids.[2A] Earlier methods included photometric and fluorometric methods.[25,91] However, they have been replaced by immunoassays* and methods based on some type of a separation step, such as capillary electrophoresis,[158,159] gas chromatography (GC),[32,208] liquid chromatography (LC),[66,120] high-performance liquid chromatography (HPLC),[120] or mass spectrophotometry (MS) interfaced with either gas (GC/MS)† or liquid (LC/MS)[23,166,184] chromatographs. These techniques are discussed in more detail in Chapters 6, 7, and 9. For routine, high-volume measurements, immunoassay is still the most widely used method because of the widespread availability of automated instruments that include immunoassays in their repertoire of analytical methods (see Chapter 9).[11,147] Many high-volume clinical laboratories, however, are now routinely using LC/MS and/or liquid chromatography/tandem mass spectrometry (LC-MS/MS)[77A,99A,176A] methods for the measurement of urinary cortisol and cortisone.

Choice of Specimen

Steroids are now measured in urine, blood, and saliva specimens.

*References 2, 57, 60, 63, 77, 94, 123, 147, 150.

Urine

Although the urinary excretion of a hormone, or its metabolites, or both does not account for the total amount of hormone secreted by the gland, it usually represents a good approximation of the amount secreted during the period of urine collection. Thus urinary assays provide a good estimate of the secretory activity of the adrenal gland. However, factors such as incompleteness of collection, altered renal function with renal disease, and the contribution by more than one gland to the total excretion pool of the same hormone or hormones (e.g., adrenal glands and gonads both contribute to the concentration of androstenedione) warrant special attention in the interpretation of urinary values. Analyses of total urinary metabolites have further shortcomings because they reflect only a fraction of the active steroid hormones that are metabolized through different pathways; the quantity and the nature of these metabolites may, in turn, depend not only on the pathological condition but on the intake of drugs and on diet. Other arguments against urinary assay of metabolites include the time and inconvenience encountered in the collection of 24-hour urine specimens. Urine assays, however, do have their place in the determination of free hormones. Urinary free cortisol and the measurement of urinary free estradiol, estrone, and testosterone have been shown to provide clinical information that reflects the production rates of these steroids.

Blood

The determination of steroids in blood has now been the accepted routine for determining the secretion rates of steroids from the endocrine organs that produce them. Immunoassays along with chromatographic methods have been developed that efficiently determine all of the clinically relevant steroids found in the circulation. In addition, because endocrine testing is founded on provocative testing (stimulation and suppression tests), blood samples for rapid dynamic testing are more convenient to obtain than urine and reflect a more relevant point in time to the patient's endocrine status. The determination of steroids in plasma, however, still has its limitations because of the rapid fluctuations and pulsatility that occur in the secretion of hormone concentrations during the day; thus a single plasma sample is representative only of the concentration that existed at the time of sampling. Therefore the measurement of some steroids, such as free cortisol, using timed urine collections still has value.

There is no experimental evidence that steroid hormone concentrations in serum are different from those in plasma. However, rapid separation of red blood cells in the specimen is important because red blood cells at room temperature can alter plasma concentrations of active steroid hormones; red blood cells degrade estradiol to estrone and cortisol to cortisone, and they can adsorb testosterone.

Saliva

In general most steroids of clinical interest can be measured in saliva.[191] For some steroids, such as cortisol, estriol, and progesterone, the measurement of the salivary concentration appears to be a reliable indicator of the free concentration in plasma. For others (e.g., testosterone, 17-hydroxyprogesterone, estradiol, and aldosterone) the clinical usefulness of salivary measurements has not yet been fully established.

It has been suggested that measurement of salivary steroids reflects the free (nonprotein-bound) steroid fraction in blood and may provide information similar to that derived from measurement of urinary free steroids.[139,148] The measurement of both cortisol and progesterone has been determined in saliva. Salivary sampling protocols are advantageous in that they allow for frequent and easy collection of samples by noninvasive, stress-free techniques. Salivary sample testing is particularly helpful when assessing hormone concentrations in children who may be averse to a needle stick. The measurement of steroids in saliva also obviates the difficulties of ensuring the completeness of a 24-hour urine collection. Patients find little difficulty in salivating directly into disposable tubes and can provide an adequate volume in ~10 minutes. Assays of samples collected at 1- to 2-hour intervals during waking hours provide an accurate assessment of baseline endocrine concentrations. Because smaller aliquots (500 μL) can be collected at 15- or even 10-minute intervals, salivary samples could well be more useful than either plasma or urine samples with short-term dynamic testing protocols. The possibilities and pitfalls of salivary hormone assays have been further discussed by Vining and McGinley.[191]

Free Versus Bound Steroids

The measurement of steroid hormones in a free state distinct from a protein-bound state may be advantageous under certain situations. When alterations in the binding proteins that carry the bulk of steroids in the circulation occur, the interpretation of the total circulating concentration of that particular steroid may be significantly influenced. In addition, it is the free hormone that binds to the steroid receptor and elicits the biochemical effect; thus knowledge of the free hormone concentration is desirable in a number of clinical situations. The concept of measuring free hormones has been in the literature for a number of years with the documented clinical utility of urinary free cortisol. Other applications include the measurement of free and weakly bound testosterone in the clinical work-up of the patient presenting with hirsutism.[139]

Hydrolysis, Extraction, and Separation

Although steroid hormones differ greatly in their physiological effects in the body, the assay procedures used for their measurement have many similarities. One or more of the following general steps may be required before final quanti-

tation: (1) hydrolysis, (2) extraction, (3) purification, and (4) separation. Note, however, that with techniques such as HPLC and with specific immunoassay methods, steps such as hydrolysis, extraction, purification, and separation are frequently unnecessary for routine clinical measurement of steroids. Improvements in antibody specificity have been the most important advance in the routine measurement of steroids, obviating the need for a purification step before immunoassay for steroids such as aldosterone, cortisol, progesterone, testosterone, and estradiol. There are still those, however, who believe that chromatography-based methods are preferable for specificity and accuracy reasons for urine steroid measurements. LC, LC-mass spectrometry (LC-MS), and LC-MS/MS methods have been developed and applied to the measurement of urinary free cortisol and other steroid hormones.

Hydrolysis

Steroid hormones are present in blood both protein bound and in a free state and excreted in the urine primarily as water-soluble conjugates of glucuronic (glucosiduronic) acid and sulfuric acid. When total concentrations (unconjugated plus conjugated forms) of a steroid hormone or its metabolites are determined, the hydrolysis of ester linkages is an obligatory step. Two general types of procedures are available, namely, acid hydrolysis and enzymatic hydrolysis. In *acid hydrolysis,* an aliquot of a 24-hour urine sample is boiled, usually with reflux, in the presence of a specified concentration of mineral acid for a specified length of time (10 to 60 minutes). For *enzymatic hydrolysis,* a portion of a 24-hour urine specimen or an aliquot of plasma is adjusted with buffer to the optimum pH for the enzyme used; after the addition of an adequate amount of the necessary hydrolytic enzymes, β-*glucuronidase* (to hydrolyze glucuronates [glucosiduronates]) and *sulfatase* (to hydrolyze sulfate conjugates), the test sample is incubated for 18 to 72 hours at a specified temperature, such as 45 °C.

Technically, acid hydrolysis is often preferred (except for acid-labile hormones), because the process offers simplicity and speed and usually results in complete hydrolysis regardless of the nature of conjugates. Enzymatic hydrolysis requires special attention to factors such as optimal concentration and type of enzyme, pH, temperature, and duration of incubation. In addition, the possible presence of enzyme inhibitors, which vary in amount and nature with different specimens, may affect the completeness of hydrolysis. In spite of potential problems, enzymatic hydrolysis is used for plasma analysis of steroids that are labile in strong acid solution (e.g., pregnanetriol and corticosteroids), and because it prevents interference from substances that are produced by acid hydrolysis. Enzymatic hydrolysis, for example, has been used successfully to determine the urine concentration of estrone and the plasma concentration of estrone sulfate in postmenopausal women.

Extraction

After hydrolysis, deconjugated steroids become sparingly soluble in aqueous solution. Thus when an immiscible organic solvent in which steroids are highly soluble is added to the hydrolyzed sample and shaken, most of the steroids are extracted into the organic layer. Repeating the extraction process with a fresh volume of the organic solvent increases the recovery of the steroid extracted. The same procedure is followed for the assay of unconjugated steroid hormones in plasma or serum. Note that addition of an organic solvent to the plasma denatures the binding proteins. Thus the extracted steroid represents both protein-bound and unbound fractions.

Selection of the organic solvent is based on the polarity of the steroid hormone to be measured. The nonpolar tetracyclic ring system is common to all steroids, but the polarity increases as the number of oxygen groups (ketone and hydroxyl groups) and double bonds increase. Steroids with one or two oxygens (e.g., androgens and estrogens) are of low polarity; a good solvent for their extraction is a relatively nonpolar solvent, such as diethyl ether. Similarly, steroids with three or more oxygen groups (e.g., corticosteroids and their metabolites) are quite polar; for their extraction, polar organic solvents such as chloroform, dichloromethane, or ethyl acetate are more suitable.

The relative solubility of substances in two immiscible solvents is used not only for the extraction process but for the separation and purification of substances (partition chromatography). The ratio of the concentration of a substance in a nonpolar phase to the concentration of the same compound in the polar phase is known as the *partition coefficient* (K) (see Chapter 6). Substances with high K values will remain in the nonpolar phase, and substances with low K values will preferentially move into the polar phase. In the extraction process, the solvent system is composed of an organic solvent (a relatively nonpolar phase) and the hydrolyzed urine or plasma (polar phase). Steroids with high Ks are consequently extracted into the organic layer. A better recovery of polar compounds (e.g., urinary corticosteroids and estriol) from the polar phase can be conveniently achieved by adding ammonium sulfate or sodium chloride before extraction. The addition of inorganic salts increases the K by decreasing the solubility of the steroid in the aqueous solution.

Purification and Separation

Although a proper choice of solvent improves the selectivity of extraction, a large number of closely related steroids, chromogenic substances, and other nonspecific materials are also extracted with the steroids. Removal of such contaminants, especially those that will interfere in the final estimation, is important when the antibody specificity used to measure the steroid is relatively low. With high specificity and high affinity antibodies, this becomes less of an issue and is now more the rule than the exception.

When the need arises to purify the steroid, the *solvent partition method* is the simplest and most suitable method for the clinical laboratory. It is widely used for preliminary purification and separation of steroid compounds of interest. The basic principle is the same as that for extraction. Steroids and other urinary impurities contained in the organic solvent are treated with weakly basic solutions (e.g., sodium bicarbonate and sodium carbonate). By virtue of their greater solubility, strongly acidic components partition into the basic aqueous layer. The separation of neutral and phenolic steroids is achieved in a similar manner. Because of the acidic nature of the phenolic steroids (estrogens), they are readily extracted from an organic phase with an aqueous solution of sodium hydroxide. After the pH of the alkaline solution is lowered, estrogens are reextracted with a suitable solvent (e.g., diethyl ether) and are processed further for final estimation. Most often the organic extract is washed to neutrality with water to ensure complete removal of alkali, which if allowed to remain might interfere in the subsequent work-up of the extract.

The degree of purification and separation needed before quantitative measurement depends on the method used for final quantitation. For example, if the final mode of estimation is a chemical reaction that is very specific for an individual steroid or for a group of steroids, further purification of the steroid extract may be omitted. In fact many of the older photometric assays for steroid hormones (e.g., urinary 17-ketosteroids) were performed on crude extracts. Similarly, with many immunoassays using highly specific antisera, the quantitation is frequently carried out without prior purification with organic extracts. Although such determinations may yield adequate information for most clinical purposes, specific measurement of an individual steroid or group of steroids may occasionally necessitate further purification and separation of the extract. Various techniques are available for this purpose. For detailed descriptions of the theory and application of these methods to steroid analysis, the reader is referred to Dorfman.[25] These methods are based on physical techniques such as countercurrent distribution, paper and column-partition chromatography, column and thin-layer adsorption chromatography, gel filtration using LH-20, GC, GC/MS, LC/MS-MS, or HPLC. Celite microcolumn chromatography is still used by many laboratories to purify and separate steroid hormones (estrone and dihydrotestosterone) before immunoassay quantitation.[118,155] Nonpolar steroids elute with low concentrations of ethyl acetate in iso-octane; more polar steroids elute as the ethyl acetate/iso-octane concentration ratio increases.

Specific Methods

Measurement of Cortisol in Blood and Urine

Approximately 90% of the circulating cortisol is bound to plasma proteins, primarily to an α-globulin known as *CBG* or *transcortin*. There is also weak binding to albumin. The exact function of these carrier proteins is still unknown, but it has been suggested that they represent a circulating storage source of hormone and protection of the steroid from inactivation and conjugation in the liver or filtration by the kidney. The concentration of CBG in the plasma rises with hyperestrogenic states, including pregnancy, and with the use of oral contraceptives; thus there is a concomitant increase of total cortisol in serum under these conditions. However, because the amount of free cortisol remains normal, there are no untoward phenotypic effects suggestive of hypercortisolism.

Although methods involving organic solvent extraction or protein precipitation will estimate both free and protein-bound cortisol in the circulation, immunoassay-based methods that determine cortisol directly from serum have essentially replaced all extraction-based methods for routine cortisol measurements save for urine free cortisol methods. Historically, four general methods have been used for the quantitative estimation of total blood cortisol concentrations in the clinical laboratory. These are the Porter-Silber color reaction method modified for plasma,[125,146] the use of sulfuric acid–induced fluorescence,[70,103] HPLC methods, or immunoassay. In general, HPLC and immunoassay are now used in both clinical laboratories and reference laboratories for the quantitative determination of cortisol in serum or urine.

Chromatographic Methods

Several types of chromatographic methods have been used to measure cortisol including GC,[32,208] LC,[59,66,88,120,183] HPLC,[102,120,130] and gas and liquid chromatography coupled to mass spectrophotometry (GC/MS* and LC/MS[23,166,184]). In addition, methods based on capillary electrophoresis have become available.[75,158,159] All of these methods easily distinguish cortisol from other steroids and steroid metabolites. However, most of them are labor intensive, have low throughput capabilities, and require considerable processing of the sample before analysis. For example, most HPLC methods require preanalytical extraction of cortisol from the specimen, with either solid-phase columns[184] or liquid-liquid extraction[94] followed by reversed-phase and normal-phase chromatography and detection using native fluorescence or ultraviolet absorption.[45,82,142] HPLC methods have the advantage of being able to separate all relevant steroids with one chromatography step, but for the practical reasons already cited are not widely used for routine purposes. Cortisol assays based on isotope dilution combined with GC/MS are widely recognized as reference procedures and are often used to validate routine methods.† In most GC/MS methods, cortisol is extracted from plasma and converted to its methoxime-trimethylsilyl derivative; deuterated cortisol is used as an internal standard.

Immunoassay

In practice, immunoassays are the easiest and most common methods used for cortisol measurements in serum and urine and are widely available in most clinical laboratories on different semiautomated and automated systems.[11,147,203]

Principle

A large number of cortisol immunoassays* have been developed using different types of antibodies[91]; processing schemes[215]; labels (both isotopic[2,60,117] and nonisotopic[63]); and measurement principles, including beta and gamma counting,[2,60] photometry,[77,84,114] fluorometry,[62,65,83,197] and chemiluminescence.[89,100,172,212] Many immunoassay methods have employed antibodies produced in animals immunized with a variety of different cortisol derivatives conjugated to protein. Antisera raised against cortisol-21-hemisuccinate and cortisol-3-carboxymethyloxime conjugates have proved quite suitable and are widely used for direct immunoassays that require no sample extraction. Specific monoclonal cortisol antibodies have also been produced using hybridoma techniques.

As mentioned earlier, most cortisol immunoassays performed in clinical laboratories are direct assays and require no initial extraction of steroids from the specimen. In these direct assays, cortisol is quantitatively displaced from endogenous binding proteins by protein-binding agents, such as 8-anilino-1-naphthalene-sulfonic acid (ANS) or salicylate, by low pH or by heat treatment.[56] The efficiency of steroid displacement by protein-binding agents, such as ANS, may be influenced by the concentration of binding protein present in the specimen. For example, the amount of ANS that is adequate for plasma obtained from normal men and nonpregnant women may be insufficient to displace cortisol from CBG in pregnancy, when CBG concentrations are elevated. Furthermore, the concentration of ANS required for complete displacement may reduce specific binding of the steroid to the antiserum.

In situations where a lower detection limit is required and highly specific antisera are not available, cortisol is first extracted from serum before measurement.[94,150] The extraction is performed in a manner similar to that for urine specimen extractions (see discussion later in this chapter).[12] An important advantage of the direct assays is their superior precision compared with assays involving extraction. In part this may reflect the variability inherent in manual extraction techniques. In general, however, with the high specificity of the antibodies available today and with the use of very sensitive nonisotopic techniques, such as chemiluminescence and fluorescence, the quantitative measurement of cortisol in blood and urine is now relatively straightforward.

Methods

Isotopic Methods. The tracer most widely used in radioimmunoassay methods for total cortisol is ^{125}I. A variety of formats have been used for the different cortisol radioimmunoassays. Some use a solid-phase first antibody to capture the cortisol, whereas others use a liquid-liquid format. Solid-phase antibodies have been chemically or physically attached to the inner or outer surfaces of test tubes, beads, or magnetizable particles. In antibody-coated tube assays, the cortisol antibody is immobilized onto the inner wall of polyethylene tubes. Test specimens and calibrators are incubated with ^{125}I-labeled cortisol in these tubes; the contents of the tubes are aspirated or decanted; and the radioactivity remaining in the tubes (^{125}I-labeled cortisol bound to antibody) is counted. This relatively quick and simple procedure does not require a centrifugation step.

Other commercial radioimmunoassay kits for serum cortisol use liquid phase double-antibody separations or solid-phase antibody suspensions. In double-antibody systems, a second antibody is used to precipitate the primary antibody, and after centrifugation and aspiration of the supernatant, the antibody-bound tracer is counted. Solid-phase suspension systems for cortisol use antibodies bound to small solid-phase particles that remain suspended in the reaction medium, thus exposing a large surface area for antibody-antigen binding and obviating the need for mixing. The suspended particles are separated by centrifugation, the supernatant is aspirated, and the bound radioactivity of the precipitate is counted.

Almost all commercial radioimmunoassay methods for serum cortisol show some cross-reactivity with prednisolone. Because prednisone is converted to prednisolone in vivo, these kits cannot be used to analyze specimens from patients on prednisone therapy. The degree of cross-reactivity with 11-DOC, corticosterone, and prednisone varies from 1% to 5%; these cross-reactions are antiserum dependent.[29] When high plasma concentrations of 11-DOC are found (such as in 11β-hydroxylase deficiency or after administration of metyrapone), preliminary extraction with carbon tetrachloride to remove this steroid is usually indicated.

In general, direct radioimmunoassays for serum cortisol are precise, sensitive, and show a high degree of correlation with reference methods such as GC/MS. According to the College of American Pathologists Ligand Assay Survey,[14] interlaboratory imprecision of the different commercial radioimmunoassay methods (expressed as coefficients of variation [CVs]) is under ±10% for serum cortisol concentrations in the range of 10 to 40 μg/dL (280 to 1100 nmol/L). Most of these radioimmunoassay methods show little bias and give results that are close to target values. Radioimmunoassay, however, is not routinely performed in clinical laboratories because of the emergence of reasonably accurate and precise nonisotopic methods for serum and urine cortisol.

Nonisotopic Methods. Most automated and semiautomated methods rely on nonisotopic labels for the quantitative measurement of cortisol. Most of these methods use enzymes such as horseradish peroxidase, alkaline phosphatase, or β-galactosidase as cortisol labels; enzyme activity is commonly determined using photometric,[77,84,114] fluorescent,[62,65,83,197] or chemiluminescent substrates.[100,172,212] Immunoassays for cortisol that use fluorescence[22,69] and chemiluminescence[89] labels are the most common methods in use today. Both heterogeneous (separation required) and homogeneous (nonseparation) methods have been developed. An example of the former is the radial partition immunoassay for cortisol.[10] In this automated assay, serum cortisol, freed from its binding proteins by ANS, competes with alkaline phosphatase–labeled cortisol for antibody binding sites on a borosilicate paper matrix. A washing procedure radially elutes unbound material while concomitantly allowing the bound enzyme to catalyze substrate cleavage. Homogeneous assays, such as fluorescence polarization immunoassay[101] and the cloned enzyme donor immunoassay[15] for cortisol, eliminate the need to separate bound and free fractions. Most immunoassay methods for cortisol are available on fully automated immunoassay systems.[11,203,147]

Specimen Collection and Storage

Serum or plasma (with heparin as an anticoagulant) can be used. No special handling procedures are necessary, and specimens may be stored refrigerated overnight at 2 °C to 8 °C. Freezing is preferred for long-term stability. Urinary free cortisol is determined on a 24-hour urine collection with or without boric acid preservative. If collected without preservative, the specimen should be refrigerated between collections and an aliquot frozen immediately after completion of the 24-hour collection.

Reference Intervals

Representative values of total cortisol (free and bound) in *serum* assayed by immunoassay are as follows:

	μg/dL	nmol/L
Cord blood[34]	5-17	138-469
Infant (1-7 days)[34]	2-11	53-304
Child (1-16 yr)[34]		
0800 hours	3-21	83-580
Adult[181]		
0800 hours	5-23	138-635
1600 hours	3-16	83-441
2000 hours	<50% of 0800 hours values	<50% of 0800 hours values

Comments

Blood cortisol concentrations parallel those of ACTH, with episodic and diurnal concentrations observed throughout the day. The blood concentration at 2000 hours is normally <50% of the concentration obtained at 0800 hours. Increased cortisol secretion is observed in patients with stress, after glucocorticoid therapy, and in pregnancy, states of depression, hypoglycemia, and hyperthyroidism. In adults there is no significant dependence of cortisol values on age or sex. The half-life of cortisol in the circulation is ~100 minutes. In the newborn period, a transient rise in cortisol occurs immediately after delivery; this is followed by a decline to a concentration below that of umbilical cord blood at 12 to 48 hours and then by an increase that stabilizes at about 1 week of age. Renal failure has little effect on serum cortisol, except that retained metabolites can cross-react in some direct assays and thus cause a significant overestimate of cortisol concentrations. Extraction of the sample with dichloromethane usually overcomes this interference. Celite chromatography has also been used to "clear" the sample of possible interference before immunoassay measurements are carried out in renal failure patients. Urine free cortisol results are influenced by a number of factors, including completeness of the 24-hour urine collection, the subject's hydration state, and renal disease.

Measurement of Free Cortisol in Blood, Urine, and Saliva

Free or unbound cortisol represents the biologically active form of the circulating hormone, and its concentration is practically independent of alterations of its transport proteins. Various methods have been developed for estimating the *free fraction in serum,* but these assays are technically demanding, expensive, and not in general use.[7,149] The measurement of *urine free cortisol* comes closest to providing an estimate of the free hormone concentration.[9] As mentioned previously, approximately 2% of cortisol is excreted into the urine in a free form, and its measurement has been shown to be of use as a screening test for cortisol hypersecretion.[136] However, β-hydroxycortisol has been reported to interfere with the immunoassay of free cortisol in urine.[80]

Free cortisol can also be measured in other body fluids, such as saliva.[71] The measurement of free cortisol in *saliva* is a practical and convenient approach to assessing the free hormone.[79,115] Salivary cortisol measurements accurately reflect the concentration of nonprotein-bound cortisol in blood (probably because of the absence of substantial amounts of transcortin or albumin in saliva), and its concentration is independent of salivary flow rate. Most immunoassay kits for total serum cortisol can be used for the measurement of cortisol in saliva[123]; extraction is not required because saliva contains virtually no cortisol-binding proteins or other cortisol metabolites. The preferred method for handling saliva samples before assaying them for their cortisol content is to quick freeze the sample on collection. With thawing and centrifugation, the glycoproteins in saliva precipitate, leaving behind a clear fluid that can then be analyzed.

Principle

Most immunoassays for total serum cortisol can be used for the measurement of urinary free cortisol after appropriate

extraction of the urine specimen. Preliminary extraction of free cortisol before measurement is usually required because of the large number of cortisol metabolites and conjugates in urine that cross-react with the cortisol antibody in the assay. Because most interfering substances are more soluble than cortisol in urine, the cortisol can be extracted with an organic solvent such as dichloromethane or ethyl acetate. Usually the sample is thoroughly mixed with the organic solvent in a ratio of ~1 : 5, the layers are allowed to separate, and the aqueous layer is removed. An aliquot of the organic layer containing the free cortisol is transferred to a separate tube, evaporated to dryness, and redissolved in a buffered solution. This solution can then be used as the unknown sample in the assay described for serum cortisol. Adding a known quantity of cortisol to an aliquot of the specimen and then extracting the spiked sample along with an aliquot of specimen to which no standard has been added can be used to monitor extraction efficiency. Extraction efficiency of cortisol is calculated from the difference in measured cortisol between the two samples divided by the known amount of cortisol added to one of the samples. The calculation of the amount of cortisol in an extracted sample must take into account the dilution with organic solvent and the extraction efficiency. Spiking the original sample with radiolabeled cortisol and determining recovery by counting the sample following the procedural steps can also determine extraction efficiency.

Immunoassay of unextracted urine is feasible with selected antisera, although reference values usually have a higher upper limit than those for extracted methods.[115] Even with solvent extraction of urine, most commercial assays for cortisol are subject to interference and show a wide range of imprecision (CV of ±15% to 25%). Chromatographic procedures, such as HPLC, are more specific than immunoassays for urine cortisol measurement and may be an attractive alternative for some laboratories.[10,59]

Urine Specimens. A complete 24-hour urine specimen is collected with 10 g of boric acid to maintain the urine pH below 7.5. Urine should be refrigerated during the collection period. After measuring the total volume, a thoroughly mixed aliquot (~10 mL) is stored frozen at −20 °C. Care should be taken to ensure an appropriately timed, complete 24-hour collection because an incorrectly timed sample is the largest source of error with this method. Free cortisol determinations on randomly collected urines are discouraged because of the variation and pulsatile characteristic of cortisol secretion.

Salivary Specimens. Cortisol is stable in saliva for 1 week at 4 °C and for 4 months when stored frozen. Freezing of specimens is recommended because it leads to precipitation of salivary glycoproteins and leaves a nonviscous liquid for pipetting.[115]

Reference Intervals

The following are representative values for free cortisol excreted per 24 hours in *urine:*

	µg/day	nmol/day	Method
Child			
1-10 yr	2-27	6-74	Radioimmunoassay (extracted)[110]
2-11 yr	1-21	3-58	HPLC[127]
11-20 yr	5-55	14-152	Radioimmunoassay (extracted)[110]
12-16 yr	2-38	6-105	HPLC[127]
Adult	20-90	55-248	Radioimmunoassay (extracted)[47]
	75-270	207-745	Radioimmunoassay (unextracted)[47]

Representative values for free cortisol in *serum* (equilibrium dialysis and/or immunochemiluminometric assay)[127] and *saliva* (radioimmunoassay)[148] of adults are as follows:

Serum	µg/dL	nmol/L
0800 hours	0.6-1.6	17-44
1600 hours	0.2-0.9	6-25
Saliva	**ng/mL**	**nmol/L**
0700 hours	1.4-10.1	4-28
2200 hours	0.7-2.2	2-6

Comments

Disadvantages of urine methods include incomplete collection owing to patient error and impaired excretion caused by renal disease. Concomitant measurement of urinary creatinine excretion allows assessment of the completeness of the collection. Salivary cortisol measurement is practical and convenient to assess cortisol secretion in ambulatory patients who can provide multiple specimens that can be stored in a freezer between clinic visits. Morning salivary cortisol concentration is decreased in adrenal insufficiency; evening values are increased in Cushing's syndrome.[135]

Measurement of Aldosterone in Blood and Urine

Simple and reliable immunoassay methods for measuring aldosterone in blood and urine[60] are readily available. These methods differ primarily in the specificity of the anti-aldosterone antibodies. Most direct radioimmunoassay methods for plasma aldosterone use antisera generated against an aldosterone-3-monooxime-bovine serum albumin (BSA) conjugate, and use an ^{125}I-labeled ligand and ANS at pH 3.6 to displace aldosterone from plasma-binding proteins.[56]

Principles

A variety of commercial immunoassay kits are available for the determination of plasma and urine aldosterone.[153,161] The

differences in these kits lie in the specificity of the antibodies used and the method used to achieve separation of bound from free aldosterone. Some methods use either a solid-phase first antibody,[164] an accelerated liquid-phase second antibody,[105] a solid-phase second antibody, dextran-coated charcoal, or a polyethylene glycol precipitant. Most assay procedures for urinary total aldosterone are similar to those for plasma except that urine is acid hydrolyzed before assay.[60]

The cross-reactivity of commercial aldosterone antisera with other steroids (e.g., DOC and corticosterone) is relatively low (<0.01%). Nevertheless, the concentration of these other steroids can sometimes be quite high, requiring the partial isolation of aldosterone before assay. Unconjugated plasma aldosterone can be extracted with an organic solvent and then purified with celite column chromatography; tritiated aldosterone is often added to each specimen to correct for procedural losses. In urine, interfering unconjugated steroids are first extracted using an organic solvent such as ethyl acetate or methylene chloride, and then the aldosterone conjugate is hydrolyzed with acid. The free aldosterone thus formed is extracted into the same solvent, the solvent is evaporated, and the radioimmunoassay is performed on the dried extract after reconstitution in an assay buffer. The need for preliminary purification depends on the diagnostic kit being used and the type of patient being evaluated. For example, specificity is not a significant concern in hypertensive adults without adrenal disease, whereas greater specificity may be needed for children, patients with adrenal disease, and pregnant women.

Several nonisotopic enzyme immunoassays have been developed for serum and urinary aldosterone using both monoclonal and polyclonal antibodies generated against aldosterone.[44,160] These assays use either immobilized antigen (aldosterone-protein complexes) or immobilized anti-aldosterone antibodies. A chemiluminescence-based immunoassay for direct measurement of aldosterone in serum has also been described.[173] In this competitive assay, the specimen is incubated for 2 hours at room temperature with a rabbit antialdosterone antibody, an isoluminol-labeled aldosterone conjugate, and paramagnetic particles coated with a second antibody. After separation and washing, the samples are incubated with sodium hydroxide for 30 minutes at 60 °C and then placed into a luminometer for a 5-second reading time. The minimum concentration of aldosterone that can be distinguished from the zero calibrator is 1 ng/dL (0.03 nmol/L), which is comparable with the detection limits of most radioimmunoassay methods. A shelf life of several years for the chemiluminescent label makes this an attractive method. Recent application of the aldosterone assay to an automated immunoassay platform will make this assay more accessible to routine clinical laboratories.

Specimen Collection and Storage

Plasma (preserved with heparin, ethylenediaminetetraacetic acid [EDTA], or citrate) or serum can be used. If an upright blood specimen is to be collected, the subject should be in an upright position (standing or seated) for at least 2 hours before collection. Specimens should be stored frozen in an airtight container and are stable for up to 2 years at −20 °C. For urine assays, a complete 24-hour urine specimen is collected with boric acid as a preservative. Fifty percent acetic acid should also be added to the urine collection to achieve a pH between 2.0 and 4.0. Specimens should not be acidified with strong mineral acids, such as hydrochloric acid. Urine should be refrigerated during collection; aliquots are stored frozen at −20 °C. It is recommended that a urine sodium test also be performed to facilitate the interpretation of the aldosterone result.

Reference Intervals

The serum, plasma, or urine concentration of aldosterone depends on the patient's salt intake and posture at the time of collection. The following serum values are based on a morning specimen collected from subjects on a normal salt diet and in an upright position for at least 2 hours[181]:

	ng/dL	nmol/L
Cord blood	0-200	1.11-5.54
Premature infants	19-141	0.53-3.91
Full-Term infants		
3 days	7-184	0.19-5.10
1 wk	5-175	0.03-4.85
1-12 mo	5-90	0.14-2.49
Children		
1-2 yr	7-54	0.19-1.50
2-10 yr	3-35	0.08-0.97 (supine)
	5-80	0.14-2.22 (upright)
10-15 yr	2-22	0.06-0.61 (supine)
	4-48	0.11-1.33 (upright)
Adults	3-16	0.08-0.44 (supine)
	5-30	0.14-0.83 (upright)

The following aldosterone concentrations excreted per 24 hours in urine have been reported[34]:

	µg/day	nmol/day	µg/g Creatinine
Newborns, 1-3 days	0.5-5	1-14	20-140
Prepubertal children, 4-10 yr	1-8	3-22	4-22
Adults	3-19	8-51	1.5-20

Measurement of 11-Deoxycortisol in Blood

With clinical evidence of an adrenal enzyme deficiency, it is customary to determine the steroid concentration just proximal to the suspected enzyme block. In the case of 21α-

hydroxylase deficiency, the measurement of 17-hydroxyprogesterone documents the enzyme deficiency. Similarly, 11-deoxycortisol measurements will confirm a 11β-hydrolyase block. A number of biosynthetic precursors of both cortisol and aldosterone can be measured by immunoassay, either directly or after sample extraction, or chromatography, or both. Other examples include pregnenolone, 17-hydroxypregnenolone, corticosterone, and DOC.

In practice the measurement of serum or plasma 11-deoxycortisol (compound S) is used to document an 11β-hydroxylase deficiency or as part of the metyrapone stimulation test. Because metyrapone inhibits the 11β-hydroxylase enzyme, a fortyfold to eightyfold increase in plasma 11-deoxycortisol is observed in patients with normal pituitary-adrenal reserve. Consequently, immunoassay methods for 11-deoxycortisol in metyrapone test specimens need not be highly sensitive. In these patients, a corresponding drop in serum cortisol is observed. A failure to demonstrate an increase in 11-deoxycortisol to at least 4μg/dL suggests either an inadequate pituitary ACTH reserve or primary adrenal failure.

Principle

Radioimmunoassay methods for the direct determination of plasma 11-deoxycortisol are available.[56,145] Antiserum raised against 11-deoxycortisol-3-carboxymethyloxime-BSA has provided appropriate specificity with minimal cross-reactivity against other adrenal steroids. Some radioimmunoassay methods still include an extraction step, or column chromatography, or both.[19,60] In one commercial kit,[29] plasma specimens are extracted with hexane and/or ethyl acetate and then assayed. Antibody-bound and free steroid fractions are separated using a double-antibody technique and polyethylene glycol precipitation. The principal interfering steroid in this kit is 17-hydroxyprogesterone (4% cross-reactivity). A few nonisotopic methods for measuring 11-deoxycortisol in serum have been described, but these procedures are not widely used.[1] Most radioimmunoassays for 11-deoxycortisol are appropriately sensitive and specific enough for use with the metyrapone test and for assessing the possibility of an 11-hydroxylase deficiency.

Reference Intervals

Representative values for 11-deoxycortisol in serum are as follows[181]:

	ng/dL	nmol/L
Cord blood	295-554	9-16
Children and adults	20-158	0.6-4.6

Measurement of 17-Hydroxyprogesterone in Blood

Measurement of serum or plasma 17-hydroxyprogesterone, a C_{21} steroid, is primarily used for the rapid diagnosis of CAH caused by the congenital absence or deficiency of the 21-hydroxylase enzyme. In classic CAH caused by 21-hydroxylase deficiency, 17-hydroxyprogesterone concentrations are several hundred times the upper limit of normal. This test is also used to monitor the effectiveness of cortisol replacement therapy in CAH patients. Measurements of 17-hydroxyprogesterone are also determined as part of the clinical work-up of women who present with hirsutism or infertility, either of which may be due to adult-onset 21-hydroxylase deficiency. This test is sometimes used after ACTH stimulation to distinguish classic affected, nonclassic affected, and heterozygote carrier individuals with the 21-hydroxylase deficiency gene.

Principle

Direct radioimmunoassays for 17-hydroxyprogesterone are available that use highly specific antibodies against 17-hydroxyprogesterone-3-carboxymethyloxime-BSA with sufficient affinity and specificity to permit direct assay of small volumes of serum, plasma, saliva, and even amniotic fluid. In addition, high–specific activity radioiodinated tracers[27,51,192] and nonisotopic labels have been used to construct enzyme immunoassays with photometric, fluorescent, and chemiluminescent substrates.[96,182] Fluorescence-based immunoassays using fluorescein or streptavidin-europium labels[33,206] and a chemiluminescence assay using an isoluminol derivative label have been described.[73] These direct assays are available in kit form[81] commercially and are convenient and simple to perform. Some are marketed with liquid calibrators. Separation of free and antibody-bound fractions is often achieved using a solid-phase coated tube or liquid-phase double-antibody methods. Despite the use of highly specific antisera, most direct assays are subject to some interference by cross-reacting substances present in neonatal and infant plasma specimens.[98] These substances increase the apparent 17-hydroxyprogesterone concentration, thereby reducing the discrimination between normal individuals and those with congenital disease. Some of the steroids that cause this interference have been identified.[205] Direct assays appear to function satisfactorily with specimens from children, adolescents, and young adults (ages 90 days to 21 years). However, for the analysis of specimens from premature neonates and infants aged 3 to 90 days, some form of extraction is recommended. Elevated results obtained by direct methods should be confirmed by reassay using an extraction method. On occasion amniotic fluid specimens are submitted for the in utero diagnosis of 21-hydroxylase deficiency in certain high-risk pregnancies. Amniotic fluid samples should be extracted before the radioimmunoassay is performed.

Specimen Collection and Storage

The preferred specimen for 17α-hydroxyprogesterone is serum; plasma with EDTA as an anticoagulant may also be used. Specimens can be stored at 4 °C for up to 4 days or at −20 °C for up to 1 month. Specimens can be obtained from infants by heel puncture and collected in capillary tubes or

on filter paper. Dried blood specimens are stable and easily transported and thus are ordinarily obtained for purposes of screening neonates for CAH.

Reference Intervals

The following serum values are representative of expected normal values for 17-hydroxyprogesterone[34]:

	ng/dL	nmol/L
Cord blood	900-5000	27.3-151.5
Premature	26-568	0.8-17.0
Newborn, 3 days	7-77	0.2-2.7
Prepubertal child	3-90	0.1-2.7
Puberty		
Tanner stage		
1. Male	3-90	0.1-2.7
Female	3-82	0.1-2.5
2. Male	5-115	0.2-3.5
Female	11-98	0.3-3.0
3. Male	10-138	0.3-4.2
Female	11-155	0.3-4.7
4. Male	29-180	0.9-5.4
Female	18-230	0.5-7.0
5. Male	24-175	0.7-5.3
Female	20-265	0.6-8.0
Adults		
Male	27-199	0.8-6.0
Female		
Follicular phase	15-70	0.4-2.1
Luteal phase	35-290	1.0-8.7
Pregnancy[186]	200-1200	6.0-36.0
Post-ACTH	<320	<9.6
Postmenopausal	70	<2.1

Measurement of Renin and Angiotensin I

The activity of the renin-angiotensin-aldosterone system is usually assessed in the clinical laboratory by measuring plasma renin activity and aldosterone concentrations. Most of the polyclonal antibodies used measure angiotensin I and are unable to distinguish between active renin and inactive prorenin. This can lead to an overestimation of renin activity and cause problems with interpretation in patients with low renin activities. However, a sensitive immunoradiometric mass assay specific for physiologically active renin has been developed using monoclonal antibodies.[168] This assay uses two monoclonal antibodies: one specifically recognizes renin but prorenin only minimally, and the other sees prorenin only with the use of the renin inhibitor remikiren. This approach may resolve the problems noted with earlier immunoassay methods for the direct determination of renin mass.

Most clinical laboratories measure PRA using an enzyme kinetic assay in which angiotensin I is formed by the action of renin on its substrate, angiotensinogen.[161,162] Angiotensin I is measured before and after a timed incubation period. The amount of angiotensin I generated from its endogenous substrate can also be quantitated using nonisotopic methods (e.g., enzyme immunoassay,[29,55,157] HPLC,[72] and fluorescence polarization[97]), but in general these approaches have not been put to large-scale use.

To obtain the maximum rate of renin activity, saturating amounts of the renin substrate, angiotensinogen, should be present in the reaction system. In most procedures, however, the only substrate provided is that present in the test plasma, and its concentration can be quite variable. According to some investigators, PRA is best estimated when the plasma specimen is incubated with an excess of exogenous renin substrate prepared from nephrectomized human subjects, oxen, or sheep. This type of assay is usually known as a plasma renin concentration assay rather than PRA assay. Unfortunately the measured renin depends on the source and concentration of the renin substrate. Synthetic peptides that resemble the *N*-terminal portion of angiotensinogen have also been used as renin substrates, but these substances can be hydrolyzed by nonspecific plasma proteases.

Several radioimmunoassays for angiotensin I and angiotensin II in native plasma have been reported, but most of them do not appear to differ significantly in their essential characteristics. Like steroid hormones, angiotensin I and angiotensin II are poor immunogens because of their small molecular size. Therefore they must be conjugated to proteins, such as albumin, hemocyanin, or succinylated polylysine, for the production of antisera. Polyclonal antisera are seldom strictly specific, and samples usually contain cross-reacting decapeptide, heptapeptide, and hexapeptide congeners of the angiotensins. In addition, plasma can continue to produce or destroy angiotensins during the assay and may contain materials that affect the assay by interfering with the antigen-antibody reaction or by binding to angiotensin itself. Isolation of angiotensin from the sample before assay has been found to minimize these problems. Acetone, methanol, ethanol, and Fuller's earth have all been used for this purpose. Other chromatographic procedures for separating and purifying the different forms of angiotensin, such as HPLC, have also been used.[49] Problems regarding cross-reactivity and interference are best eliminated by using sensitive and specific antisera.

Angiotensin II, the active peptide of the renin-angiotensin system, is the most difficult component of the renin cascade to measure accurately. Most immunoassay methods are unable to detect the very low concentrations in blood, and interfering peptides or degradation products must be removed before radioimmunoassay. An additional chromatographic separation step is usually required to distinguish angiotensin II from other angiotensins. However, monoclonal antibodies with high affinity and specificity have been produced against angiotensin II and used to develop a direct radioimmunoassay; as little as 0.8 fmol of angiotensin II in 2 mL of plasma has been detected in the presence of angiotensin I.[167]

Sealey[162] and Freedlender and Goodfriend[36] have reviewed the special problems encountered in the preparation of plasma specimens for radioimmunoassay of angiotensins. Angiotensins are very labile peptides in plasma and can be generated in vitro in untreated plasma even in the frozen state. Therefore great care must be taken in the collection and storage of specimens for angiotensin assays,[49] including special attention to the inactivation of the cleavage enzymes, angiotensinases.

A number of commercial kits are available for determining PRA[161,162]; the basic elements of these procedures are summarized in the following sections. With continued improvements and availability of the immunometric assay methods for determining renin mass, renin activity assays will likely be replaced by the direct mass assays for the routine assessment of plasma renin.

Principle

PRA is defined as the rate of angiotensin I produced from the substrate angiotensinogen by the enzyme renin in a patient's plasma. PRA is expressed in nanograms of angiotensin I generated per milliliter of plasma per hour and is determined by measuring angiotensin I after incubation of plasma at 37 °C and then subtracting the amount of baseline angiotensin I in a control plasma aliquot kept at 4 °C.

Specimen Collection and Storage

A blood sample is drawn into a lavender-top vacutainer tube containing EDTA. After centrifugation to sediment cells, the plasma is removed and frozen at −20 °C or lower. Plasma for PRA can be stored frozen up to 1 month before assay. Freeze-thaw cycles should be avoided because of the possible activation of prorenin. At the time of collection, blood should not be chilled or placed on ice because irreversible cryoactivation of prorenin can occur, leading to falsely high estimates of PRA. Serum or plasma collected into another anticoagulant can also be used as long as EDTA is added (3 mmol/L, final concentration) before the angiotensin I generation step. It should be recognized, however, that prorenin is more likely to cryoactivate in serum than in plasma. Uncentrifuged blood is stable at room temperature for up to 6 hours without significant accumulation of angiotensin I. Hemolyzed specimens should not be used because red blood cells contain angiotensinases. Heparin should be avoided as an anticoagulant for this reason. The use of EDTA is preferred for PRA because it not only acts as an anticoagulant but also inhibits the ACE and other hydrolytic enzymes that break down angiotensin.

Factors such as time of day, posture, salt intake, and diuretic or other drug use should be properly documented for appropriate interpretation of test results. The patient should be ambulatory for 2 hours before blood collection. A 24-hour urine specimen for sodium is collected on the day before the renin test to reference the result to salt intake. Specimens with high renin activity can generate considerable amounts of angiotensin I before and during storage even at −20 °C. This will not affect results, however, because angiotensin I is determined before and after the incubation step. An angiotensinase enzyme inhibitor is used in the reaction system to prevent further metabolism of angiotensin I. The buffering of plasma samples is also important because any change in pH alters the generation of angiotensin I at 37 °C. Most PRA assays use a pH that is optimum for the renin enzyme (5.7 to 6.3). The baseline angiotensin I concentration obtained at 4 °C is subtracted from the angiotensin I concentration generated after 60 to 90 minutes of incubation at 37 °C. The time of incubation varies depending on the sensitivity of the angiotensin I antiserum and the amount of renin activity. Most assays use an incubation period of 60 minutes with satisfactory results, but the time of incubation can be extended to improve the sensitivity of the assay. Subtracting the baseline angiotensin I value normalizes the result to endogenous angiotensin I concentrations, but this can be a source of error particularly when renin activity is low. Some investigators ignore the blank when the baseline angiotensin I result exceeds the generated angiotensin I concentration.[162]

Angiotensin I Generation

Angiotensin I is generated using the following procedure:

1. Thaw frozen specimens in front of a fan for a few minutes until they are at room temperature. Do not thaw frozen specimens in a refrigerator.
2. Add one or more of the following inhibitors to thawed plasma: phenylmethyl sulfonyl fluoride, 8-hydroxyquinoline sulfate, dimercaprol, and neomycin (see Comments section for explanation of the use of inhibitors).
3. Add the maleate generation buffer (pH 6.0) to each plasma specimen.
4. Divide the plasma mixture into four aliquots.
5. Incubate two aliquots for 60 to 90 minutes at 37 °C (see Comments section for discussion of choice of period of incubation) and store the other two aliquots at 4 °C.
6. At the end of the incubation period, chill the aliquots in an ice bath at 4 °C.
7. The incubated and nonincubated aliquots are then assayed for angiotensin I. Incubated plasma represents the endpoint of renin activity, whereas the 4 °C plasma represents renin activity at baseline.
8. Renin activity is then calculated as nanograms of angiotensin I produced per milliliter of plasma per hour of incubation, adjusting for the volume of plasma, the time of incubation, and the difference in angiotensin I concentrations between the incubated and nonincubated samples.

Comments

Phenylmethyl sulfonyl fluoride added to thawed plasma inhibits angiotensinases that can cleave the generated angiotensin I but are unaffected by metal chelators.

The other inhibitors help retard proteolysis and bacterial growth.

Plasma specimens must be buffered. Otherwise, the pH will increase during enzymatic incubation at 37 °C, in which case the rate of angiotensin I generation will decrease owing to a shift in the kinetics and to the destruction of renin above pH 8. Thus assays use a buffer near the pH optimum of renin (5.7 to 6.3).

Reference Intervals

Reference intervals for PRA vary depending on salt intake, posture, and certain medications. For adults on a normal sodium diet, a reference interval of 0.7 to 3.3 ng of angiotensin I/mL/hr has been reported.[181] Sodium intake, posture, hydration state, and other factors that can affect renin activity should be noted. For example, a low-sodium diet and upright posture increase renin activities in normal individuals. High renin values may also be seen in patients receiving diuretics (volume and sodium depletion) or estrogen-containing medications (stimulation of hepatic synthesis of angiotensinogen).[116] Most antihypertensive drugs alter PRA, and such drugs should be discontinued 1 to 2 weeks before the test is performed. Only stimulated PRA values (e.g., after furosemide stimulation) are of practical value in evaluating hypertensive patients.

Plasma renin activity decreases gradually with age in both men and women. In women, renin activity is increased during the luteal phase of the menstrual cycle and in pregnancy.

CHAPTER 52

The Thyroid: Pathophysiology and Thyroid Function Testing*

Laurence M. Demers, Ph.D., F.A.C.B., D.A.B.C.C., and Carole Spencer, Ph.D.

The *thyroid* is a butterfly-shaped gland located in the front of the neck just above the trachea that weighs approximately 15 to 20 grams in the adult human. The fully developed thyroid gland in a human is composed of two lobes connected by a thin band of tissue, the *isthmus,* which gives the gland the appearance of a butterfly. The gland is closely attached to the trachea in the anterior aspect of the neck. Each lobe measures ~2.0 to 2.5 cm in thickness and width and ~4.0 cm in length. The isthmus measures ~2.0 cm in length and width and ~0.5 cm in thickness.

The secretory units of the thyroid gland are follicles that consist of an outer layer of epithelial cells. These cells rest on a basement membrane and enclose an amorphous material called *colloid.* Colloid is mainly composed of thyroglobulin (an iodinated glycoprotein) and small quantities of iodinated thyroalbumin. The follicles are embedded in stromal tissue, which contains blood vessels and autonomic nerve fibers. Increased activity of the gland is characterized by a decrease in the quantity of colloid with subsequent reduction of follicular volume; the lining cells become columnar and may even proliferate into the colloid. During decreased glandular activity, the follicles enlarge because of the accumulation of colloid and the flattening of follicular cells. The cytoplasm of the follicular cells has a microtubular network, and microvilli that extend from the apices of these cells into the colloid. The important reactions of thyroid hormone synthesis, such as iodination and the initial phase of hormone secretion (colloid resorption), are believed to take place at or near the apical surface of the cell. Thyroid follicular cells, like cells of other endocrine glands, have a prominent endoplasmic reticulum.

The thyroid gland also contains another type of cell known as *parafollicular* or *C cells.* These cells have been shown to produce the polypeptide hormone *calcitonin* (see Chapter 49). These cells never border the follicular lumen but are confined within the follicular basement lamina or exist in clusters in the interfollicular spaces.

THYROID HORMONES

CHEMISTRY

The thyroid gland secretes two hormones, thyroxine (3,5,3′,5′-L-tetraiodothyronine) and triiodothyronine (3,5,3′-L-triiodothyronine), which are commonly known as T_4 and T_3, respectively (Table 52-1). In addition, the thyroid gland secretes small amounts of biologically inactive 3,3′,5′-L-triiodothyronine (reverse T_3 [rT_3]) and minute quantities of monoiodotyrosine (MIT) and diiodotyrosine (DIT), which are precursors of T_3 and T_4. The structures of these compounds are shown in Figure 52-1.

Approximately 40% of the secreted T_4 is deiodinated by peripheral tissues by enzyme deiodinases to yield T_3, and about 45% is deiodinated to yield rT_3. Therefore, with a normal T_4 production of ~100 nmol (80 μg) daily, approximately 40 nmol (26 μg) of T_3 and 45 nmol (29 μg) of rT_3 are produced by peripheral deiodination. From the esti-

TABLE 52-1 Nomenclature and Abbreviations for Thyroid Tests

Hormone Concentration	
Total thyroxine	T_4
Total triiodothyronine (3,5,3′-triiodothyronine)	T_3
Free thyroxine*	FT_4
Free triiodothyronine*	FT_3
Thyrotropin (thyroid-stimulating hormone)	TSH
Reverse T_3 (3,3′,5′-triiodothyronine)	rT_3
Estimates of Free Hormone Fraction	
Free T_4 fraction†	% FT_4
Free T_3 fraction†	% FT_3
Thyroid hormone binding ratio‡	THBR
Estimates of Free Hormone Concentration	
Free T_4 estimate [$T_4 \times$ % FT_4]	FT_4E
Free T_3 estimate [$T_3 \times$ % FT_3]	FT_3E
Free T_4 index [$T_4 \times$ THBR]	FT_4I
Free T_3 index [$T_3 \times$ THBR]	FT_3I
T_4/TBG ratio	T_4/TBG
Free T_4 estimate (by immunoassay)§	FT_4E
Serum Binding Proteins	
Thyroxine-binding globulin	TBG
Thyroxine-binding prealbumin (transthyretin)	TBPA
Tests for Autoimmune Thyroid Disease	
Antithyroglobulin antibodies	TgAb
Antimicrosomal antibodies	TMAb
Antithyroid peroxidase antibodies	TPO Ab
TSH receptor antibodies	TRAb
Other Hormones and Thyroid-Related Proteins	
Thyrotropin-releasing hormone	TRH
Thyroglobulin	Tg
Calcitonin	CT

*Measured by "direct" immunoassay of a dialysate (or ultrafiltrate) of undiluted serum.
†Measured by equilibrium dialysis (or ultrafiltration) of diluted serum containing tracer T_4 or T_3.
‡Derived from T_3 or T_4 "uptake" methods (see text for details).
§Measured by two-step or analog (one-step) assays.

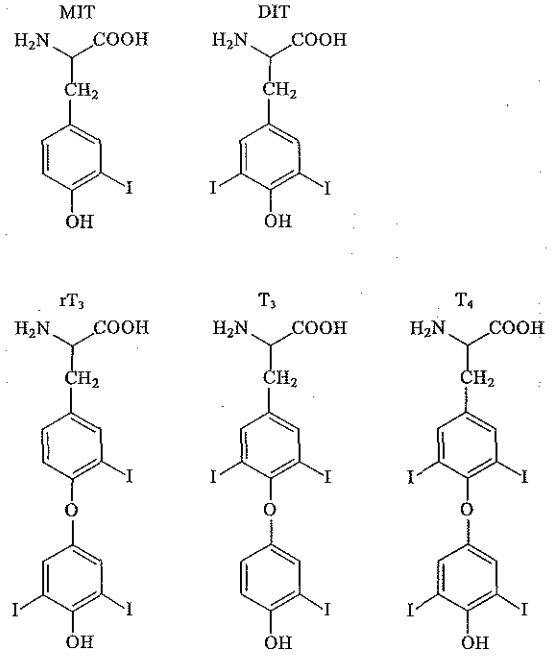

Figure 52-1 Structure of thyroid hormones and their precursors. *MIT,* Monoiodotyrosine; *DIT,* diiodotyrosine; rT_3, 3,3′,5′-L-triiodothyronine; T_3, 3,5,3′-L-triiodothyronine; T_4, 3,5,3′,5′-L-tetraiodothyronine.

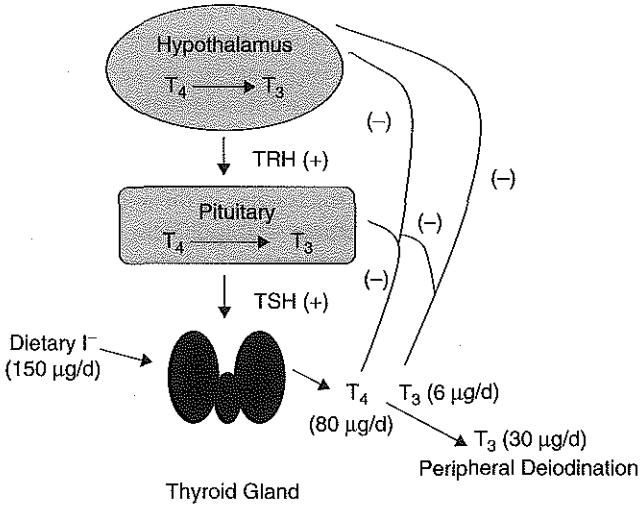

Figure 52-2 Hypothalamic-pituitary-thyroid axis—hormone synthesis dependent on dietary intake of 150 µg of iodine per day. T_4 major thyronine secreted from thyroid gland with T_3 coming predominantly from peripheral deiodination.

mated daily production rates for T_3 (30 µg) and rT_3 (30 µg), it is evident that in a euthyroid state at least 85% of T_3 production and essentially all of rT_3 production are accounted for by peripheral deiodination of T_4 rather than by direct secretion by the thyroid gland (Figure 52-2). T_3 is four to five times more potent in biological systems than T_4. Because one third of all T_4 is converted to T_3 during the course of its metabolism, T_4 is considered to be a prohormone without any intrinsic biological activity.

Biological Function

Thyroid hormones have many important biological effects.[13] A major function is their control of the basal metabolic rate and calorigenesis through increased oxygen consumption in tissue via the effects of thyroid hormone on membrane

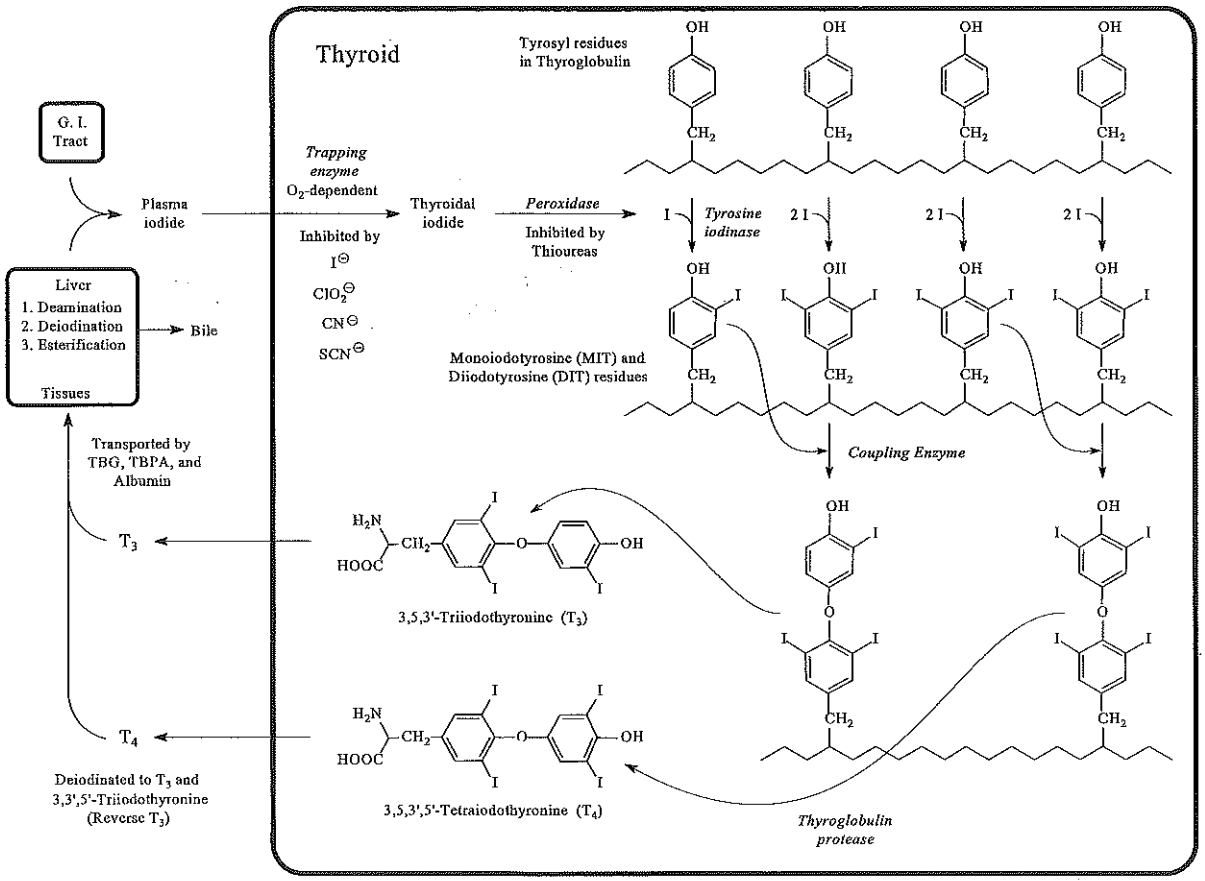

Figure 52-3 Formation and secretion of thyroid hormone. Iodine transport into the gland is inhibited by anions such as thiocyanate (SCN^-), perchlorate (ClO^{-4}), and pertechnetate (TcO_4^{-1}). The oxidation and organic binding of iodide to thyroglobulin are blocked by thioureas, sulfonamides, and high concentrations of iodide. *(Modified from Berger S, Quinn JL. Thyroid function. In: Tietz NW, ed. Fundamentals of clinical chemistry, 2nd ed. Philadelphia: WB Saunders Co, 1976:585.)*

transport (cycling of Na^+/K^+-ATPase with increased synthesis and consumption of adenosine triphosphate) and enhanced mitochondrial metabolism (stimulation of mitochondrial respiration and oxidative phosphorylation). Thyroid hormones are indispensable for neural development, normal growth, and sexual maturation in mammals. Other actions include stimulation of adrenergic activity with increased heart rate and myocardial contractility, stimulation of protein synthesis and carbohydrate metabolism, increased synthesis and degradation of cholesterol and triglycerides, increased requirement for vitamins, increased calcium and phosphorus metabolism, and enhanced sensitivity of adrenergic receptors to catecholamines. These effects are typically magnified in patients with hyperthyroidism and subdued in patients with hypothyroidism.

Biochemistry

The biosynthesis of thyroid hormones involves the trapping of circulating iodide (iodide transport) by the thyroid gland, the incorporation of iodine into tyrosine, and the coupling of iodinated tyrosyl residues to form the thyronines (T_4 and T_3) within the protein backbone of the thyroglobulin protein in the follicular lumen. Endocytosis followed by proteolytic cleavage of thyroglobulin releases the iodothyronines into the circulation. A schematic outline of iodine metabolism, with emphasis on the formation and secretion of thyroid hormones, is shown in Figure 52-3.

Dietary iodine is the basic element involved in the synthesis of thyroid hormones; it is normally ingested in the form of iodide. Iodide transport to the follicles is the first and rate-limiting step in the synthetic process. The follicular cells of the thyroid concentrate iodide to some 30 to 40 times the normal plasma concentration by means of an energy-dependent pump mechanism. Upon stimulation of the gland by the pituitary hormone thyroid-stimulating hormone (TSH; MW 30 kDa; also called *thyrotropin*), or with blockade of iodide uptake by antithyroid drugs such as propylthiouracil or methimazole, the glandular iodide concentration can reach 800 times the plasma iodide concentration. Other anions are attracted to the thyroid gland and can act as competitive inhibitors of iodide uptake and transport. Two clinically useful anions are pertechnetate

TcO_4^{-1} and perchlorate (ClO^{-4}). The ability of perchlorate to inhibit iodide transport is the basis for its use in the so-called perchlorate-discharge test used to detect defects in thyroid gland–binding and uptake of iodide. The use of radioactive pertechnetate is also the basis for thyroid gland imaging studies used to evaluate patients with suspected thyroid disease. The salivary glands, gastric mucosa, placenta, ciliary body of the eye, choroid plexus, and mammary glands are also capable of transporting iodide against a concentration gradient, but this uptake does not come under the influence of TSH. The physiological significance of this extrathyroidal iodide-concentrating mechanism is not well understood.

Iodide is oxidized at or near the thyroid gland membrane to a more reactive iodine, probably as the free radical of iodine, I•; within seconds, the active iodine is bound to tyrosine molecules attached to a thyroidal protein called *thyroglobulin* (Tg; 660 kDa). Tg is also synthesized within the follicular cells of the gland before being secreted into the follicular lumen by exocytosis. The enzyme responsible for the oxidation and binding of iodide (organification) is thyroid peroxidase (TPO); hydrogen peroxide accepts the electron. Initially, monoiodotyrosine and diiodotyrosine (MIT and DIT) molecules are formed (see Figure 52-3). Two DIT molecules then undergo an oxidative condensation with the release of an alanine residue for the formation of T_4, which is still in peptide linkage to Tg. Similarly, T_3 is produced from the coupling of MIT and DIT. A small amount of rT_3 is also formed, probably by condensation of DIT and MIT. The condensation reaction is an aerobic, energy-requiring reaction, and like oxidation and binding, is considered to be catalyzed by TPO. Iodide thus bound to tyrosine residues can no longer be discharged by thiocyanate, perchlorate, or other inhibitors of iodide transport.

The synthesis of T_3, T_4, DIT, and MIT in Tg molecules occurs mainly at the follicular cell–colloid interface but also within the colloid. Tg is present in highest concentrations within the colloid, where it is stored. The follicular cells engulf colloid globules by endocytosis; these globules then merge with lysosomes in the follicular cell. Lysosomal proteases break the peptide bonds between iodinated residues and Tg, and T_4, T_3, DIT, and MIT are released into the cytoplasm of the follicular cell. T_4 and T_3 diffuse into the systemic circulation after their liberation from Tg. DIT and MIT are deiodinated by an intracellular microsomal iodotyrosine dehalogenase. The freed iodide is then reused for thyroid hormone synthesis.

Each step in the synthesis of thyroid hormones is regulated by pituitary TSH. TSH stimulates the "iodide pump," Tg synthesis, and colloidal uptake by follicular cells. TSH also regulates the rate of proteolysis of Tg for the liberation of T_4 and T_3 is also regulated by TSH. In addition, TSH induces an increase in the size and number of the thyroid follicular cells. Prolonged TSH stimulation leads to increased vascularity and eventual hypertrophic enlargement of the thyroid gland (goiter).

Metabolism

Metabolism of T_4 to T_3 and the transport of these two thyroid hormones in the blood are discussed later in this section. The degradative metabolism of T_3 and T_4 occurs by oxidative deamination, which produces pyruvic acid analogues that are ultimately converted to thyroacetates by a decarboxylation reaction. These analogues have some residual biological activity, but there is no evidence that they are physiologically significant. In the liver, T_3 and T_4 are conjugated to form sulfates and glucuronides. These conjugates enter the bile and pass into the intestine. Thyroid hormone conjugates are hydrolyzed, and some are reabsorbed (enterohepatic circulation) or excreted in the stools. The amounts of thyroidal substances in the urine are very small, and urinary assays to measure these substances have little clinical value. For a thorough discussion of thyroid metabolism, secretion, and synthesis, the reader is referred to a chapter by Larsen and Ingbar.[115]

Physiology

A tightly controlled feedback system exists between the thyroid gland, the hypothalamus, and the pituitary gland (Figure 52-2).[113] The function of these three glands is closely integrated, resulting in thyroid hormone concentrations in blood being maintained within certain limits in the face of large changes in basal metabolism and physiological need for thyroid hormone. Thyrotropin-releasing hormone (TRH), a tripeptide, is produced in the hypothalamus. TRH acts on the pituitary thyrotropes to stimulate both the synthesis and release of TSH.[92] TSH in turn controls the thyroid gland and the synthesis and release of thyroid hormones. TSH also controls the size and number of thyroid follicular cells. A rise in the thyroid hormone concentration elicits an inhibitory effect on the pituitary response to TRH (negative feedback). Conversely, a fall in thyroid hormone concentrations causes an increase in both TRH and TSH secretion (positive feedback).

Free (unbound) T_4 is the primary secretory product of the normal thyroid gland. T_4 is progressively degraded by deiodination and ether-link cleavage to form its intrinsic thyronine and tyrosine core molecules. Only 5′ deiodination of T_4 is an activation step and leads to the production of a metabolically active metabolite (T_3). All other deiodinations are inactivating. The T_4 deiodination cascade to form T_3, rT_3, MIT, and DIT derivatives is catalyzed by three types of selenodeiodinase enzymes (Type 1, Type 2, and Type 3). T_4 to T_3 conversion is catalyzed by both Type 1 and 2 deiodinases. These enzymes coexist in the same tissue, but generally have different tissue distributions (hepatic versus nonhepatic, Type 1 versus Type 2, respectively). In hypothyroid and euthyroid conditions, circulating T_3 is primarily derived from Type 2 enzymes, whereas when T_4 substrate is high (i.e., hyperthyroidism) T_3 production is primarily derived from Type 1 enzymes. Type 3 deiodinases that catalyze the inner-ring deiodination of T_4 to produce metabolically inert rT_3 are considered important for controlling the amount of

maternal thyroid hormone delivered to the developing fetus (see Figure 52-3). Type 1 deiodinase activity is inhibited during acute or chronic stress or illness and with a number of medications. Inhibition of Type 1 deiodinase activity causes a decrease in circulating T_3 secondary to decreased production and an increase in rT_3 secondary to reduced clearance; however the total T_4 concentration remains essentially unchanged.

When released by the thyroid gland, T_4 and T_3 are carried in the circulation bound to carrier proteins. These carrier proteins (T_4-binding globulin [TBG], T_4-binding prealbumin [TBPA], and albumin) bind 99.97% of T_4 and 99.7% of T_3. Thus only a very small fraction of each of these hormones circulates unbound and is free for biological activity. The largest concentration of protein-bound hormone acts as a reservoir for T_4 to maintain a constant concentration of free T_4 (FT_4). Because of the wide variation in the concentration of T_4-binding proteins, even under normal circumstances, there is a wide variation in total T_4 concentrations among euthyroid individuals (i.e., those having normal thyroid function). Total T_3 concentrations also vary with alterations in the concentration of the binding proteins, although to a lesser degree than T_4 concentrations. Common situations in which the thyroid hormone-binding protein concentrations are increased or decreased are shown in Box 52-1. When relying on the measurement of total thyroid hormone concentrations to diagnose thyroid hormone excess or deficiency states, knowledge of possible changes in binding proteins can be extremely important. The measurement of FT_4, however, obviates this need since free hormone concentrations are independent of the binding protein concentration.

BOX 52-1 Alterations in the Concentration or Affinity of Thyroid Hormone-Binding Proteins

Increases in:

A. TBG concentration (or affinity)
   1. Genetic (inherited) causes
   2. Nonthyroidal illness (HIV infection, infectious and chronic active hepatitis, estrogen-producing tumors, acute intermittent porphyria)
   3. Normal physiology (pregnancy, newborn)
   4. Drug use (oral contraceptives, estrogens, tamoxifen, methadone)
B. Prealbumin concentration
C. Albumin binding (familial dysalbuminemic hyperthyroxinemia)
D. T_4 binding by antibodies (autoimmune thyroid disease, hepatocellular carcinoma)

Decreases in:

A. TBG concentration
   1. Genetic (inherited) determination
   2. Nonthyroidal illness (major illness or surgical stress, nephrotic syndrome)
   3. Drug use (androgens, anabolic steroids, large doses of glucocorticoids)
B. TBG binding capacity (drugs bound to TBG such as salicylates and phenytoin)
C. Prealbumin concentration

THYROID DYSFUNCTION

Hypothyroidism and hyperthyroidism are the two primary pathological conditions that involve the thyroid glands.[6] Laboratory testing of thyroid hormones is used to diagnose and document the presence of thyroid disease, a condition that often presents with vague and subtle symptoms. Accurate measurement of thyroid hormone concentrations is key to the proper diagnosis of thyroid gland dysfunction.[169,216]

HYPOTHYROIDISM

Hypothyroidism is defined as a deficiency in thyroid hormone secretion and action.[44] It is a common disorder that occurs in mild or severe forms in 2% to 15% of the population.[164] Women are afflicted more often than men, and both sexes are affected more frequently with increasing age. Clinical symptoms can range from the obvious and easy-to-recognize lethargy, fatigue, and cold intolerance to more subtle, subclinical disease with general symptoms that escape detection. Figure 52-4 depicts the constellation of physiological events associated with decreased thyroid hormone availability. *Myxedema* is a severe form of hypothyroidism in which there is accumulation of mucopolysaccharides in the skin and other tissues, leading to a thickening of facial features and a doughy induration of the skin.[84] *Cretinism* is the term used to describe severe hypothyroidism that develops in the newborn period.

Many structural or functional abnormalities of the thyroid gland can lead to thyroid hormone deficiency (Box 52-2). Primary hypothyroidism is frequently caused by diseases or treatments that directly destroy thyroid tissue or interfere with thyroid hormone biosynthesis. Secondary hypothyroidism occurs as a result of pituitary or hypothalamic disease and/or disorders.

Primary Hypothyroidism

Primary goitrous hypothyroidism results when the synthesis of T_4 and T_3 is impaired, either because of some extrinsic factor or because of an intrinsic, inherited defect in thyroid hormone biosynthesis. As a result, the positive feedback loop causes compensatory thyroid enlargement (goiter) through the hypersecretion of TRH and TSH. Primary nongoitrous hypothyroidism is characterized by loss or atrophy of thyroid tissue, resulting in decreased production of thyroid hormones despite maximum stimulation by TSH. Hashimoto's thyroiditis is the most frequent cause of primary hypothyroidism in developed countries where iodine intake is sufficient. Worldwide, iodine deficiency is the most common cause of goitrous hypothyroidism. The

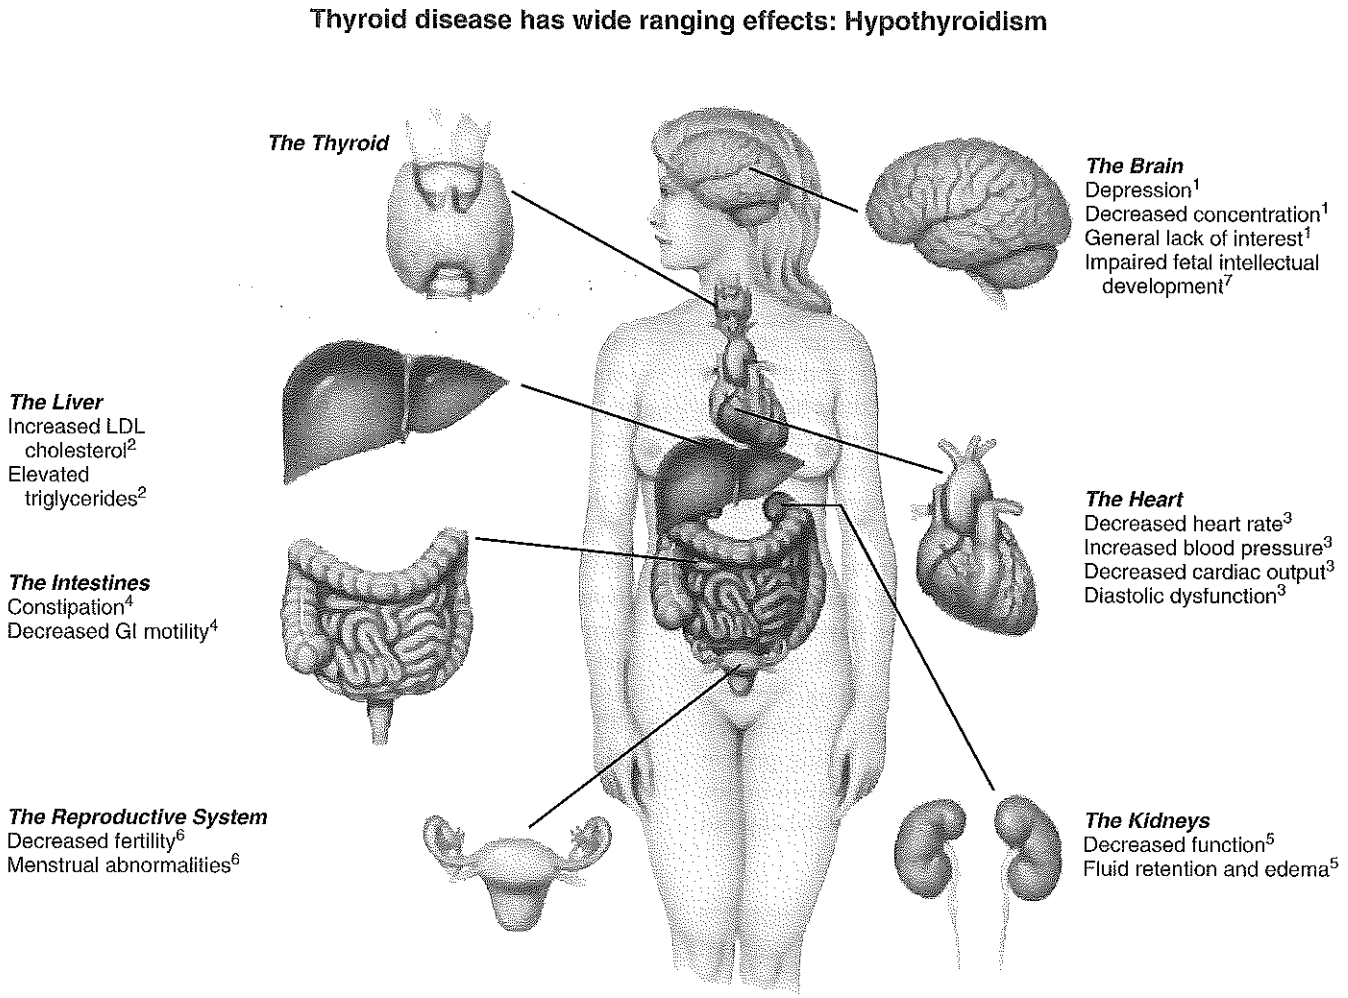

Figure 52-4 The clinical effects of hypothyroidism on different organ systems.

most common cause of nongoitrous hypothyroidism is surgical removal or radioablation of the thyroid gland in the treatment of Graves' disease. Primary hypothyroidism is frequently associated with circulating antithyroid antibodies and may coexist with other diseases in which autoantibodies are found. In addition, primary hypothyroidism may be one manifestation of an autoimmune syndrome of polyglandular endocrine failure.[221]

Reduced concentrations and availability of T_4 and T_3 lead to hypersecretion of pituitary TSH and marked elevations in serum TSH concentrations. The elevated concentration of TSH is an important laboratory finding, particularly in the early detection of thyroid failure. In mild or subclinical hypothyroidism, thyroid hormone concentrations can remain within the normal reference interval, but the TSH concentration is elevated. The etiology of primary hypothyroidism is usually determined on the basis of a good history, a physical examination, and the tests for circulating thyroid autoantibodies.

Congenital hypothyroidism that is recognized at birth may be caused by the complete absence of the thyroid gland (athyreosis) itself or can occur secondary to defects in thyroid hormone synthesis. This disorder occurs once in every 3500 to 4000 live births, and early treatment with thyroid hormone replacement is critical if irreversible neurological damage is to be prevented.[41,45,64,116] Screening programs for congenital hypothyroidism have been established in almost all developed countries of the world.[77,112] Initially North American programs used a two-tiered laboratory approach in which an initial T_4 measurement is obtained followed by a measurement of TSH in specimens with low T_4 values. In most programs, T_4 is measured in blood eluted from a filter paper spot collected from the newborn infant using a heel stick. Floating cutoff values are set high enough to preclude false-negative results. In general, when T_4 results are outside the lower 10th to 20th percentile of the normal distribution, a TSH measurement on another specimen from the same filter paper spot is then performed. In most instances, the diagnosis of congenital hypothyroidism in the neonate can be made at this time; in some cases, further testing is needed on follow-up. Alternatively European and Japanese programs favor screening by means of TSH mea-

BOX 52-2 Causes of Hypothyroidism

Primary (Thyroidal) Hypothyroidism

A. Loss of functional tissue
   1. Chronic lymphocytic (Hashimoto's) thyroiditis
   2. Radiation injury to the neck (I-131 therapy, radiotherapy)
   3. Postoperative hypothyroidism (neck surgery)
   4. Thyroid gland dysgenesis, developmental defects (neonatal)
B. Infiltrative disease of the thyroid
   1. Viral infections
   2. Bacterial infections
C. Defects in thyroid hormone synthesis
   1. Congenital biosynthetic defects
   2. Endemic iodine deficiency
   3. Drug-induced defects (lithium, glucocorticoids, iodine, propranolol)
   4. Idiopathic primary hypothyroidism (TSH receptor defect)
   5. Antithyroid agents (propylthiouracil [PTU])
   6. Thyroiditis with autoantibodies

Hypothyrotropic (Secondary) Hypothyroidism

A. Pituitary disease—TSH deficiency
B. Hypothalamic disease—TRH deficiency

Peripheral Resistance to Thyroid Hormones

BOX 52-3 Causes of Hyperthyroidism

Common Causes of Thyroid Hyperfunction*

A. Diffuse toxic hyperplasia (Graves' disease)
B. Toxic multinodular goiter (Plummer's disease)
C. Toxic solitary adenoma

Less Common Causes of Thyroid Hyperfunction†

A. Acute or subacute thyroiditis (viral or bacterial etiology)
   1. Hashimoto's (autoimmune) thyroiditis
   2. De Quervain's thyroiditis (subacute)
   3. Lymphocytic thyroiditis (painless, subacute)
B. TSH-secreting pituitary tumor
C. Thyroid carcinoma (papillary, follicular, anaplastic)
D. Postpartum thyroiditis
E. HCG-secreting trophoblastic tumor
F. Iodine-induced hyperthyroidism
G. Iatrogenic thyrotoxicosis factitia
H. T_3 toxicosis
I. Drug-induced thyrotoxicosis (amiodarone)
J. Ectopic thyroid tissue (struma ovarii, thyroid carcinoma metastases)

*Associated with increased radioactive iodine uptake, except iodine induced.
†Associated with decreased radioactive iodine uptake.

surements followed by T_4 determinations on infants with TSH values elevated above 20 mIU/L.* Many newborn screening programs in the United States have switched or are considering a switch to the first TSH approach.

Primary hypothyroidism is easily treated by the daily administration of oral thyroxine.[185] During initial treatment, serum FT_4 concentrations adjust quickly, but TSH concentrations remain high. Because the pituitary is slow to register acute changes in thyroid hormone status ("pituitary lag"), 4 to 8 weeks may be needed for serum TSH values to reach a new steady state after dose adjustments. Periodic monitoring of serum TSH, one to three times a year, is recommended to help maintain clinical euthyroidism and a serum TSH concentration within normal limits.[173] Excessive treatment with oral T_4 should be avoided to minimize the risk of accelerated bone resorption and/or atrial fibrillation.

Secondary Hypothyroidism

Secondary hypothyroidism (central thyroid disease) occurs as a result of pituitary or hypothalamic diseases that produce a deficiency in either TSH, TRH, or both. Isolated TSH deficiency is rare, and most patients with secondary hypothyroidism also have other pituitary hormone deficiencies as well (panhypopituitarism). With secondary hypothyroidism, the serum concentration of thyroid hormone is low, but TSH concentrations are either low or within the normal reference interval. When T_4 and TSH concentrations are both low, a TRH test may offer some benefit. In patients who have destructive lesions of the pituitary gland that result in TSH deficiency, no TSH response is expected with exogenous TRH administration. In patients with hypothalamic abnormalities that affect TRH and TSH release, the peak TSH response to TRH may be normal, but is generally delayed until 45 or 60 minutes after the TRH administration rather than after the usual time of 20 to 30 minutes.

*The reader should note that "U" had been reserved by chemists for the international unit of enzyme activity. However, U is often used to mean a unit of TSH concentration as defined by the WHO. To avoid confusion with enzyme activity units, "IU" and "int units" are used in this chapter to refer to the units of TSH concentration.

HYPERTHYROIDISM

Hyperthyroidism is defined as a hypermetabolic condition caused by excessive production of thyroid hormones.[44] This disorder is caused by a number of conditions resulting from excess availability of thyroid hormones (Box 52-3).[14,96] Some clinicians prefer the general term *thyrotoxicosis* rather than hyperthyroidism to define the hypermetabolic state associated with increased amounts of thyroid hormone in the circulation. Figure 52-5 depicts the metabolic changes associated with increased availability of thyroid hormone. Causes of thyrotoxicosis are divided into two types: (1) those associated with frank hyperthyroidism and increased production and secretion of thyroid hormones from the gland, and (2) those that are not. In North America, the most

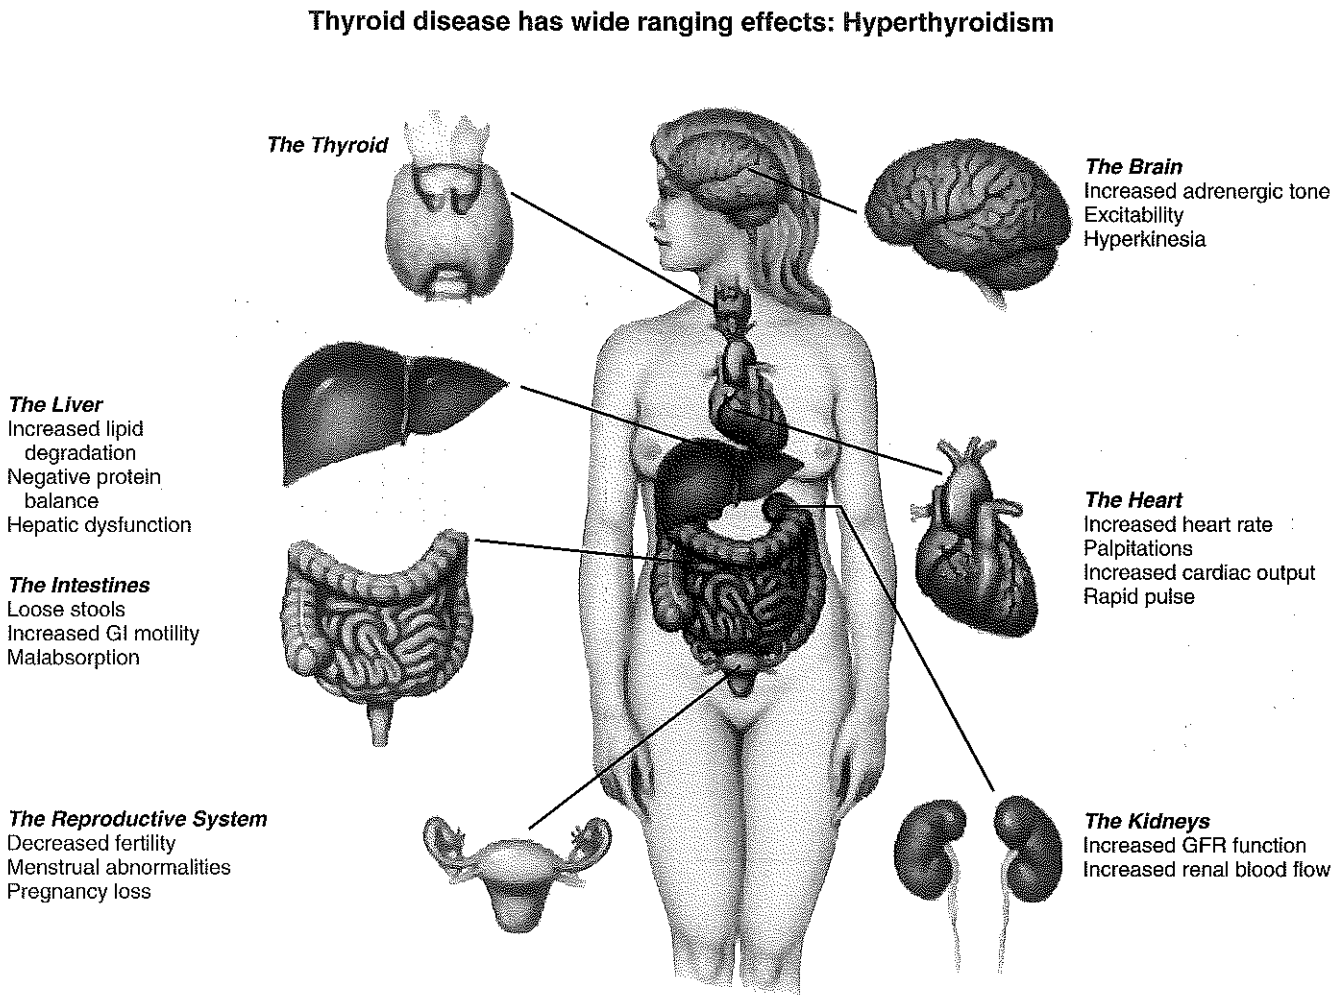

Figure 52-5 The clinical effects of hyperthyroidism on different organ systems.

common cause of thyrotoxicosis due to hyperthyroidism is Graves' disease, an autoimmune disorder that affects 0.4% of the U.S. population; its etiology involves the development of an IgG antibody against the thyroid TSH receptor, resulting in overproduction of T_4 and T_3 by the thyroid gland. Overproduction of thyroid hormones can also result from autonomous production by solitary or multiple thyroid nodules, from a toxic solitary adenoma, or from excessive TSH secretion by pituitary tumors (rare). Less common causes of hyperthyroidism include acute and subacute thyroiditis caused by viral or bacterial infections that affect the thyroid gland itself, producing increased leakage of stored hormone from the gland as a result of inflammatory changes and white cell infiltration. New hormone synthesis can be decreased due to suppression of TSH secretion by the hormone excess. Other secondary causes of hyperthyroidism include exogenous intake (thyrotoxicosis factitia) of thyroid hormone, iodide ingestion in excess, thyroid carcinoma, and drug-induced thyrotoxicosis with medications such as amiodarone.

The prevalence of hyperthyroidism is fairly low in the general population (0.3% to 0.6%) and women are more prone to developing hyperthyroidism than men, with the ratio of females to males with Graves' disease being 5:1. Hyperthyroidism is often easier to diagnose on clinical observations than is hypothyroidism (Box 52-4). In some patients with hyperthyroidism, particularly individuals older than 60 years of age, the diagnosis may not be self-evident, and symptoms may be dismissed or attributed to stress or other causes. The biochemical picture of primary hyperthyroidism shows increases in T_4 and T_3, with a TSH suppressed to undetectable concentrations, except in those rare cases in which hyperthyroidism is mediated by TSH itself (e.g., TSH-secreting pituitary adenoma or pituitary resistance to thyroid hormones). Patients with hyperthyroidism typically have serum TSH concentrations less than 0.05 mIU/L. A serum TSH within the euthyroid reference interval almost always eliminates the diagnosis of hyperthyroidism.

When the TSH concentration is suppressed, the serum FT_4 concentration should be measured and will be elevated in most cases of hyperthyroidism. Finding a low TSH concentration and an elevated FT_4 concentration is usually sufficient to establish the diagnosis of hyperthyroidism. If the TSH concentration is low but the FT_4 concentration is

BOX 52-4 Symptoms of Hyperthyroidism and Hypothyroidism

Hyperthyroidism
- Weight loss
- Fatigue
- Nervousness
- Palpitations
- Rapid pulse
- Menstrual irregularities
- Heat intolerance
- Increased sweating
- Diarrhea
- Restlessness
- Tremor
- Muscle weakness
- Eye changes (Graves' disease)
- Variable gland enlargement

Hypothyroidism
- Weight gain
- Easy fatigue
- Lethargy
- Cold intolerance
- Hair loss
- Constipation
- Depression
- Slow reflexes
- Slower heart beat
- Hoarseness/deepening of voice
- Dry, patchy skin
- Elevated cholesterol
- Puffy eyes
- Menstrual irregularities
- Muscle weakness/cramps

within the normal reference interval, a T_3 measurement should be performed, because serum T_3 concentration is often elevated to a greater degree than is T_4 in the early phases of Graves' disease and in some patients with solitary or multinodular toxic goiters (so-called T_3 thyrotoxicosis). A persistently suppressed serum TSH concentration in the face of normal concentrations of serum T_3 and FT_4 could signify "subclinical hyperthyroidism," a defined biochemical entity with few or subtle clinical symptoms. Because only the free fraction of T_3 is biologically active, the estimation of a free T_3 (FT_3) is helpful to compensate for variations in binding proteins. A number of medications and acute and chronic illnesses cause a transient lowering of T_3 concentrations. In patients with nonthyroidal illnesses (NTIs), an early diagnosis of hyperthyroidism may not be possible until the other illness has resolved.

Occasionally, increases in serum concentrations of T_4 and T_3 will occur as a result of the ingestion of large quantities of exogenous thyroid hormones or to the release of thyroid hormones as a result of damage to the thyroid parenchyma associated with subacute thyroiditis or chronic lymphocytic thyroiditis. The increase in T_4 and T_3 concentrations may be associated with clinical findings that suggest true hyperthyroidism. This diagnostic dilemma, however, can be resolved by finding a low radioactive iodine uptake (percent of orally administered radioactive iodine taken up by the gland at 6 or 24 hours) that accompanies these nontoxic forms of hyperthyroidism. In most cases of thyroiditis, the condition is self-limited and will resolve without residual thyroid function abnormalities.

Until sensitive TSH assays became available, the most conclusive test for hyperthyroidism was the TRH stimulation test. Patients with high concentrations of circulating thyroid hormone have an active negative feedback loop that blocks the release of TSH from the pituitary gland. In a patient with vague but suggestive symptoms of hyperthyroidism and T_4 or T_3 concentrations that are not clearly elevated, failure of the TSH concentration to rise after TRH administration establishes the diagnosis of hyperthyroidism. The TRH test is rarely used for the diagnosis of hyperthyroidism now that sensitive TSH assays are able to distinguish the profoundly suppressed TSH concentrations in true hyperthyroidism from the mild transient depressed TSH concentrations that occur in patients with other nonthyroidal conditions, such as an acute or chronic illness. Patients with a nonthyroidal illness will often have a suppressed TSH but the concentration is still detectable with current TSH methodology. Treatment strategies for hyperthyroidism include (1) administration of antithyroid drugs, (2) radioiodine ablation, and (3) surgical removal of the thyroid gland itself. Treatment is typically designed to decrease thyroid hormone production or inhibit peripheral conversion of T_4 to T_3.[185] At the time treatment is initiated, measurements of serum FT_4 are recommended every few weeks until symptoms abate and serum values normalize; continuous monitoring for recurrence of hyperthyroidism is suggested two or three times a year after successful therapy.[173] Because the pituitary gland is suppressed in hyperthyroidism, measurement of the concentration of serum TSH is not a good monitor of thyroid status in the immediate period following the start of antithyroid therapy. In fact, TSH concentrations remain suppressed for months after the patient becomes clinically euthyroid. Ablation of thyroid tissue or overtreatment with antithyroid drugs sometimes leads to clinical hypothyroidism and an increase in serum TSH; surveillance for hypothyroidism in previously treated hyperthyroid patients must continue for the life of the patient and can best be monitored with a serum TSH.

Nonthyroidal Illness

Many disorders are associated with thyroid hormone excess or deficiency in the absence of definable thyroid disease. These states of euthyroid hyperthyroxinemia or euthyroid hypothyroxinemia often result from alterations in the concentration of thyroid hormone–binding proteins, the actions

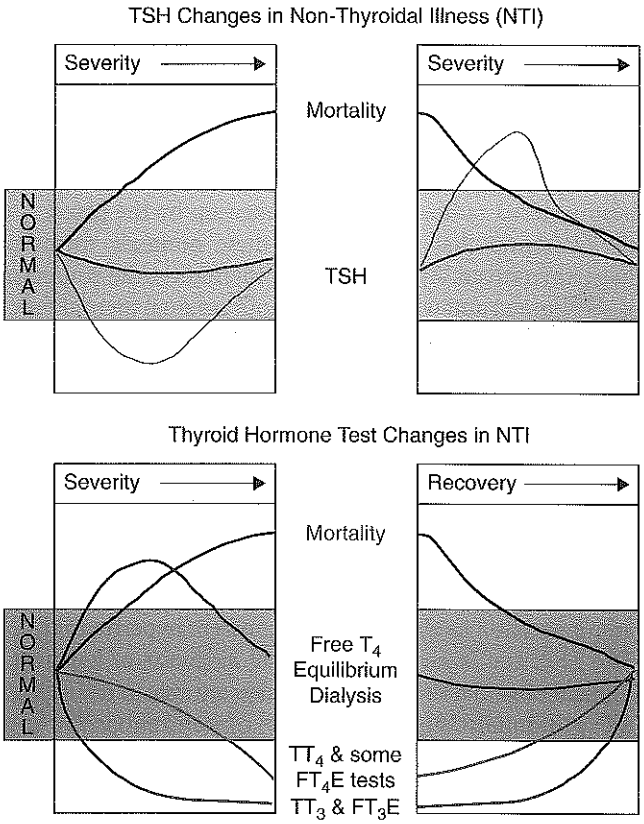

Figure 52-6 The spectrum of thyroid hormone concentrations with illness.

of certain drugs, the effects of acute and chronic NTIs, or peripheral resistance to thyroid hormones.

A progressive spectrum of thyroid test result anomalies accompanies NTIs in euthyroid patients (the "euthyroid sick syndrome")[25,135,201,219] (Figure 52-6 and Box 52-5). The earliest and most common changes that occur are a reduction in the serum concentrations of total and free T_3, sometimes to extremely low concentrations, and an elevation in the serum concentration of rT_3 (the "low T_3 state"). These changes have been ascribed to a block in the 5′deiodinases that convert T_4 to T_3 in peripheral tissue. Acute and chronic nutritional problems, poorly controlled diabetes mellitus, and drugs such as hydrocortisone and beta blockers can also inhibit this conversion.

Declining concentrations of total T_4 may also be seen in NTIs; however, FT_4 concentrations, determined by immunoassay and by equilibrium dialysis, usually remain within the normal reference interval or are found to be mildly elevated. This disparity between falling total T_4 values and normal, or even elevated, free T_4 concentrations may be caused by decreases in serum concentrations of thyroid hormone–binding proteins, changes in binding properties induced by circulating inhibitors and drugs, or both. Unfortunately, some methods for estimating FT_4, such as the one-step immunoassays, may provide artifactually low results in euthyroid patients with increasing severity of chronic illness.

BOX 52-5 Effects of Acute and Chronic Illness on Thyroid Function

Reduced peripheral conversion of T_4 to T_3
Increased production of rT_3
Reduced production of thyroid hormone–binding proteins
Circulating inhibitors of thyroid hormone binding
Mild elevation of serum TSH during recovery phase
Mild depression of serum TSH during acute phase

Conversely, some methods give artifactually high results in some circumstances, such as IV heparin administration.

Serum TSH concentrations are usually normal in euthyroid sick patients, but may be mildly to moderately depressed during the acute phase of NTI or slightly elevated during recovery from a severe illness.[75] Causes of these transient abnormal TSH concentrations are not fully understood but may relate to the effects of endogenous or exogenous hormones, such as glucocorticoids or dopamine, which independently suppress pituitary TSH secretion, altered nutrition, or altered biological activity of immunoreactive TSH.[7]

As patients recover from NTIs, many of the thyroid test abnormalities revert to normal. Total T_4 concentrations will be corrected first followed by a rise in T_3. Serum TSH may also transiently rebound to high concentrations for several days or weeks before returning to normal. Thus, in NTI, abnormal thyroid function test results do not necessarily indicate the presence of thyroid disease, but may demonstrate adaptations to the catabolic state. Conversely, paradoxically normal values may be seen in patients with thyroid disease as a result of medications or nonthyroidal illness per se. Assessments of thyroid function in ill patients are best postponed until the illness resolves, unless a diagnosis would affect patient outcome.

Hypothyroidism Versus Euthyroid Sick Syndrome

The most common dilemma presented by the thyroid test result aberrancy seen with the euthyroid sick syndrome occurs when hypothyroidism is suspected in an ill patient. Total and FT_3 concentrations are expected to be low in nonthyroidal illness and should not be measured for this purpose. If the total or FT_4 concentration is normal, hypothyroidism is unlikely; however, a reduced total T_4 and a slightly subnormal FT_4 estimate may be seen in extremely ill euthyroid patients. Serum TSH is probably the best single test to distinguish between euthyroid sick syndrome and hypothyroidism (in the absence of suspected pituitary or hypothalamic disease or medications, such as dopamine or glucocorticoids). A clear elevation of the TSH concentration (>20 mIU/L) would indicate hypothyroidism. Lesser TSH elevations may be seen transiently in euthyroid sick syndrome patients during recovery. Increasing the upper limit of the TSH reference limit to 8 or 12 mUL in critical illness has

been suggested to improve the specificity for hypothyroidism with minor loss of sensitivity.[40] Dopamine or glucocorticoids also suppress pituitary TSH release and may result in a normal TSH concentration in a hypothyroid patient. If the question of hypothyroidism in acutely ill patients cannot be resolved with TSH and FT_4 testing, measurement of rT_3 may help (rT_3 being low in hypothyroidism [either primary or secondary] and normal or high in euthyroid subjects). Documentation of a normal serum cortisol may help distinguish euthyroid sick syndrome patients from those with hypothalamic or pituitary hypothyroidism.

Hyperthyroid Versus Euthyroid Sick Syndrome

As many as 3% of hospitalized patients on admission have subnormal TSH values often associated with the acute phase of illness or with glucocorticoid or dopamine therapy. With more sensitive TSH assays, most (~75%) hyperthyroid patients have profoundly low TSH values (less than 0.01 mIU/L) compared with critically ill euthyroid patients with only mild transient suppression of TSH in the 0.05 to 0.1 mIU/L range.

Effect of Drugs

A number of medications have been shown to alter thyroid function and thyroid function tests.[38,186,202] Few drugs are associated with the development of clinically significant thyroid disease (amiodarone may be an exception), but difficulty in the interpretation of thyroid function tests results when patients are placed on medications that affect thyroid function testing. In general, drugs do not interfere chemically with the assays for thyroid hormones or TSH. The medications most likely to affect TSH concentrations are glucocorticoids and dopamine (reduced TSH concentrations) and amiodarone (increased TSH concentrations). The most commonly encountered variations in thyroid hormone measurements induced by medications are reduced peripheral conversion of T_4 to T_3 or altered binding of T_4 and T_3 to carrier proteins. Some of the medications that affect thyroid function tests are shown in Table 52-2.

Diagnosis of Thyroid Dysfunction

Laboratory tests most commonly used to evaluate patients for thyroid gland dysfunction are listed in Table 52-1. Familiarity with normal physiology and with pathophysiology is important if these tests are to be properly used and selected. However, it is important to note that normal serum thyroid hormone concentrations do not exclude thyroid disease, and abnormal thyroid tests do not always indicate thyroid disease. Diffuse or nodular thyroid enlargement, for example, may be seen in euthyroid patients.[111]

The clinical signs and symptoms of thyroid hormone excess or deficiency are generally vague and nonspecific (see Box 52-4). Therefore when hypothyroidism or hyperthyroidism is suspected, confirmation with laboratory tests is generally required. Guidelines for the selection of appropriate laboratory tests for thyroid function have been published by professional organizations such as the American Thyroid Association (www.thyroid.org),[69A,185,204] the National Academy of Clinical Biochemistry[37,173] (www.nacb.org), and the Royal College of Physicians in London.[220,214] Several algorithms have been published for thyroid function testing, including an algorithm used in a large hospital in Detroit.[58] For a thorough discussion of the diagnosis and treatment of thyroid disease, the reader is referred to general endocrine texts[13,39,115] or reviews on specific topics, such as cardiac disease,[170] disturbances in menstruation,[104] fetal disorders,[63] general thyroid disease,[7,217] hypothyroidism,[45,68,123,224] hyperthyroidism,[78,117,118,174,177] mood disorders,[56] and pregnancy.[17,71,91,137,140]

Historically, thyroid testing was performed stepwise, with the initial step being either a total serum T_4 measurement or a free thyroxine estimate (FT_4E) using, for example, the FT_4 index. Total T_4 measures both bound and free hormone and reflects thyroid hormone production; however, changes in the concentration or affinity of serum thyroid hormone–binding proteins affect total T_4 concentrations without changing the free, active hormone ("abnormal" total T_4 test results in the absence of thyroid disease). Mild changes in serum binding proteins, such as those induced by pregnancy or estrogen therapy, can be corrected with an indirect estimate of FT_4 by immunoassay (FT_4E); extreme binding protein abnormalities, however, can give artifactual FT_4E results. Elevated protein concentrations tend to produce an overestimation of the FT_4E result, whereas low protein concentrations produce an underestimation of the FT_4 value. For patients with primarily TBG abnormalities, an FT_4E provides more reliable diagnostic information than does a total T_4 value alone. If necessary, in some circumstances when equivocal results are obtained, the FT_4 concentration may be measured directly using equilibrium dialysis methods.

Total T_4 and FT_4E measurements are not ideal indicators of thyroid status, in part because of the effects of variations in serum binding protein concentrations, but also because T_3 is the biologically active and most potent form of thyroid hormone and because the relationships between these hormones (T_4 and T_3) are not always predictable. In patients with hyperthyroidism, T_3 is usually elevated to a greater extent than T_4 because it is derived from two sources: increased thyroidal secretion of T_3 and increased peripheral conversion of T_4 to T_3. The measurement of total T_3 is sometimes a useful adjunct test in patients suspected of hyperthyroidism. However, because T_3 concentrations fluctuate rapidly in response to stress and other nonthyroidal factors, T_3 concentrations are low not only in hypothyroidism, but also in many other conditions. Thus the routine measurement of total T_3 is not a good screening test of thyroid status.

The serum concentration of TSH reflects the integrated action of thyroid hormones at the concentration of one of its target tissues—the pituitary cells that secrete TSH. Thus measurement of TSH is more reliable in the diagnosis of

Philadelphia: JB Lippincott, 1995:299-306; Stockigt JR. Thyroid hormone changes in critical illness: The sick euthyroid "syndrome." Diag Endo Metab 1997;15:39-46.

↓ reduced serum concentration; ↑ increased serum concentration; ↔ no change.

thyroid gland dysfunction than is the measurement of thyroid hormone concentrations themselves. Pituitary TSH secretion is exquisitely sensitive to circulating thyroid hormone concentrations; in fact, a twofold change in FT_4 can elicit a 100-fold change in the serum TSH concentration.[99,190] This reciprocal log-linear relationship, shown in Figure 52-7, explains why some patients may have normal concentrations of FT_4 or FT_3, or both, and few clinical signs or symptoms of thyroid dysfunction, but may have TSH concentrations that are abnormally high or low. Not all such "subclinical" thyroid disease warrants treatment, but detection of mild changes in thyroid function may be important for some patients.

In the past, clinical use of TSH measurements was limited by the inability of most immunoassays to differentiate the lower limit of normal from abnormally low concen-

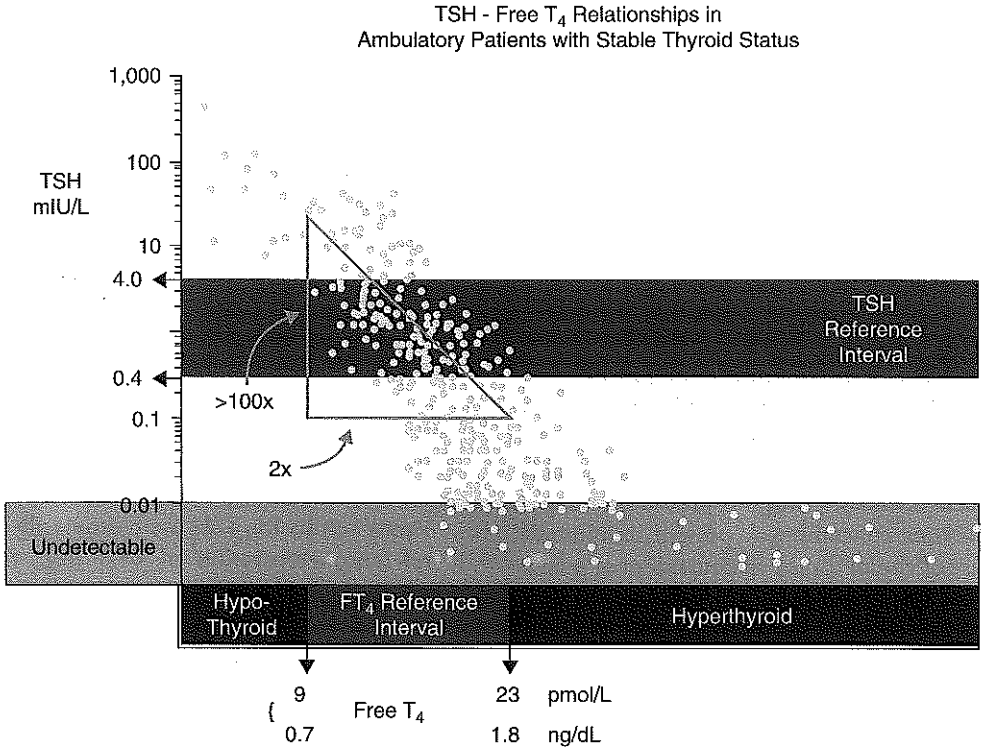

Figure 52-7 The log-linear relationship between TSH and FT_4. A twofold change in TSH is associated with an approximate 100-fold change in circulating FT_4 concentrations. *(Modified from Spencer CA, LoPresti JS, Patel A, Guttler RB, Eigen A, Shen D, et al. Applications of a new chemiluminometric thyrotropin assay to subnormal measurement. J Clin Endocrinol Metab 1990;70:453-60. Copyright 1990, The Endocrine Society.)*

trations. Improvements in assay technique have led to the availability of so called third generation high sensitive TSH assays that distinguish low from normal concentrations. These new assays have altered the approach to thyroid function testing. Instead of screening for thyroid disease with an FT_4E test, a sensitive TSH assay is now the accepted initial screening test of thyroid function in ambulatory patients; TSH concentrations are elevated in hypothyroidism and low in hyperthyroidism. FT_4 testing can be ordered in a reflex fashion when the TSH concentration is abnormally high or low (Figure 52-8). This TSH-centered strategy for the initial evaluation of thyroid function has proven to be both cost-effective and medically efficient.[8,192]

ANALYTICAL METHODS

As the laboratory assessment of thyroid disease has been refined through the wide-scale availability of improved techniques and commercial kits, some confusion in terminology has developed. Table 52-1 is a review of the nomenclature for tests of thyroid hormones and thyroid-related proteins in serum. Guidelines for the classification of various thyroid tests have been further described in a special report of the American Thyroid Association.[114]

Almost all laboratory tests for thyroid function are commercially available in kit form and on automated immunoassay platforms. The following is a brief description of tests that are considered useful for the evaluation of thyroid status. With space limitations, literature citations are representative, but not inclusive. For detailed descriptions of methods, refer to original reports or to the documentation accompanying commercial products.

Determination of Thyroid-Stimulating Hormone in Blood

The measurement of TSH was originally based on bioassays such as the stimulation of colloid droplet formation in the guinea pig thyroid gland and the release of labeled thyroidal iodide into mouse blood.[32] These early in vivo bioassays, however, were of limited sensitivity and precision and were not applicable to the measurement of TSH in unfractionated serum. Most TSH bioassays have involved the in vitro stimulation of thyroid cyclic adenosine monophosphate (cAMP) or adenylate cyclase activity. The rat FRTL-5 thyroid cell line is an example of a particularly convenient and precise assay system.[211] Unfortunately, such methods require purification and concentration of TSH from serum before assay. Sensitive detection of TSH in unfractionated serum is possible using a cytochemical bioassay,[158] but this procedure is technically difficult and time-consuming. At present, immunoassay is the procedure of choice for the measurement of serum TSH in the clinical laboratory.

Principle

The first immunological assay for TSH was based on the cross-reaction of human and bovine TSH in a hemagglutination inhibition test;[121] however, this method was too insensitive for clinical purposes. Immunoassay measurement of serum TSH concentration did not become a routine test until the purified pituitary hormone became available for immunization and iodination.

Radioimmunoassay

The traditional radioimmunoassay (RIA) for TSH was based on competition between endogenous and radiolabeled hormone for binding sites on a limited amount of antibody. Separation of antibody-bound and free radioligands was conveniently performed by double-antibody precipitation (enhanced by the addition of polyethylene glycol) or by using a solid-phase, second-antibody procedure. The amount of labeled TSH bound to the antibody was inversely related to the amount of unlabeled TSH present in the serum specimen.

The determination of serum TSH by RIA proved very valuable in assessing the elevated TSH values in primary hypothyroidism. However, because these assays could only detect 1 mU of TSH per liter, most conventional RIAs could not distinguish normal values from the subnormal values associated with hyperthyroidism.

Immunometric Assays

Immunometric methods based on chemiluminescence are capable of measuring TSH at concentrations required to accurately detect the low concentrations of serum TSH found in patients with true hyperthyroidism or the suppressed concentrations found in patients with nonthyroidal illnesses. These sensitive methods resulted from the application of the immunometric sandwich configuration, in which a serum TSH molecule forms a bridge between two or more distinct anti-TSH antibodies. The first antibody (of monoclonal origin) is often directed at the specific TSH beta subunit and is anchored to a solid-phase separation system. This antibody is present in excess and selectively immunoextracts the majority of TSH molecules from the serum specimen. Bound hormone is then quantitated using a second TSH antibody (of either monoclonal or polyclonal origin) that is directed against a distinctly different antigenic site on the TSH molecule. This detection antibody is labeled with a signal molecule such as a luminescent molecule. In some immunometric assays, the separation antibody is attached to plastic beads, test tube walls, microtiter plates, magnetizable particles, or glass fiber paper (see Chapters 9 and 11). Another variation is to attach biotin to the antibody and separate the TSH complex using avidin linked to a solid phase.[152]

Assay results for TSH are customarily calibrated against a reference preparation of TSH (e.g., the World Health Organization's Second International Reference Preparation [2nd IRP] 80/558) and expressed as milliinternational units of biological activity per liter of serum (mIU/L). In contrast to the inverse dose-response curve found in RIA, immunometric assays have a positive dose-response curve, with higher concentrations of signal corresponding to higher concentrations of TSH. High-dose hook effects are rarely found. Immunometric assays offer not only improved sensitivity for TSH measurement, but also rapid turnaround time and a wider linear measurement range as compared with traditional RIA methods.

Immunometric assays for TSH are available commercially as manual kit procedures or for use on automated systems. For practical reasons, nonisotopic methods dominate the market and have replaced radioactive tracer methods in most routine laboratories. The majority of immunometric TSH assays label the detection antibody with chemiluminescent labelled molecules[52,138,160]; other labels include peroxidase or alkaline phosphatase and sensitive photometric[42,66] and fluorescent[42,66,154,168] molecules. Other assays are based on the use of fluorescent labels using europium chelates[95,162]; chemiluminescent compounds such as acridinium esters[109] or ruthenium[87]; or bioluminescent molecules such as recombinant aequorin.[165]

To distinguish immunometric TSH assays from less sensitive RIAs, descriptive terms such as "sensitive," "highly sensitive," "ultrasensitive," and "supersensitive" have been used, generating much confusion as to the exact meaning of these terms. In 1991, a Nomenclature Committee of the American Thyroid Association recommended that the *functional detection limit* of serum TSH assays be determined on the basis of low-end interassay precision characteristics.[80] Further, the committee recommended that precision at the lower reporting limit should optimally be 10% to 15% and preferably <20%. At present, functional sensitivity is defined as the lowest concentration of TSH at which an interassay coefficient of variation of 20% can be achieved.[171,195] This functional detection limit encompasses both analytical and

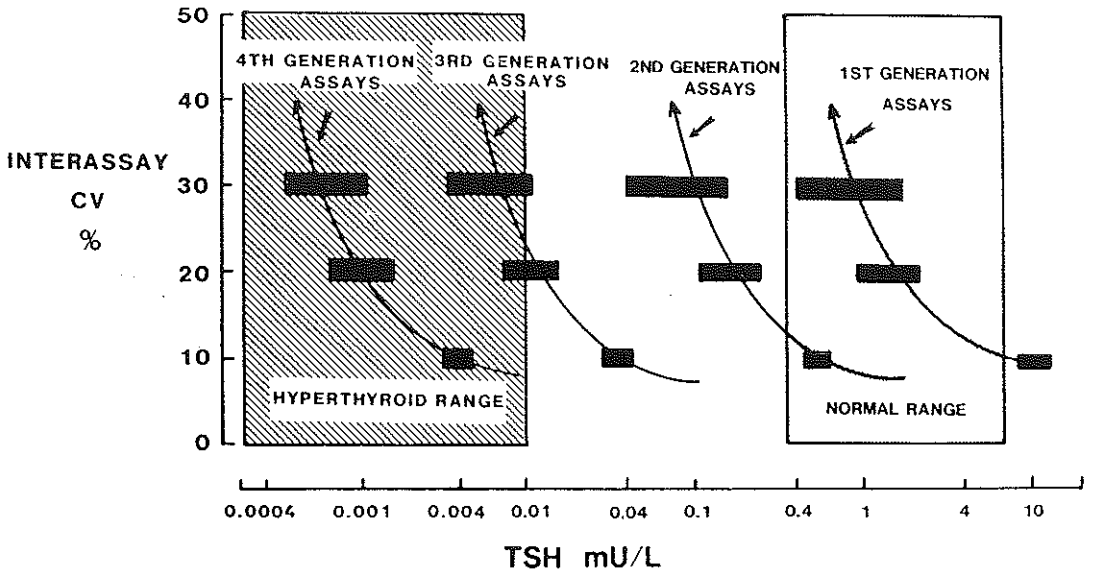

Figure 52-9 Schematic representation of the generation system of nomenclature for TSH assays based on interassay precision (% coefficient of variation). Each generation represents a tenfold improvement in functional sensitivity (20% interassay coefficient value). The black bars denote the 95% confidence limits of measurement at different TSH concentrations. *(Modified from Nicoloff JT, Spencer CA. The use and misuse of sensitive thyrotropin assays. J Clin Endocrinol Metab 1990;71:553-8.)*

biological variations and ensures that the measured TSH concentration is different from zero. Some manufacturers claim a detection limit for their assays that is based on intraassay precision of duplicates of the zero calibrator (i.e., the least detectable concentration). Unfortunately, this detection limit is sometimes overly optimistic. However, the American Thyroid Association has determined that only TSH assays with third generation functional sensitivity can be used as first line thyroid tests.[111A]

A "generational" classification based on functional sensitivity has been suggested to describe improvements in TSH assays[153,190] (Figure 52-9). Each generation of assay represents one log improvement in its detection limit. First generation RIAs typically had a functional detection limit of 1 to 2 mIU/L. The subsequent immunometric assays had about a tenfold improvement in their functional detection limit (0.1 to 0.2 mIU/L) and are considered second generation TSH assays. Second generation assays can reliably distinguish normal from hyperthyroid (or hypothyroid) values in ambulatory patients; however, they have limited value for distinguishing mildly subnormal values (0.02 to 0.1 mIU/L) from the very low values (<0.01 mIU/L) that are typical of thyrotoxicosis.

Third generation immunometric assays have been developed for TSH measurements that have enhanced precision at even lower detection limits. Most of these assays use chemiluminescence-based technologies and have a functional detection limit of less than 0.02 mIU/L. Fourth generation assays having a functional detection limit of 0.001 to 0.002 mIU/L range also have been developed.[196]

Different approaches have been used to implement chemiluminescence-based assays.[132] For example, one assay configuration consists of a polystyrene tube coated with a monoclonal capture antibody and a polyclonal detection antibody conjugated with an acridinium ester; this ester emits a flash of light on treatment with hydrogen peroxide and sodium hydroxide.[193] Another approach uses an antibody-coated tube, a polyclonal antibody conjugated to alkaline phosphatase, and an adamantyl dioxetane phosphate ester as substrate; on dephosphorylation, the substrate decomposes and emits a sustained glow of light.[15] Cross-reactivity of this TSH assay with luteinizing hormone, follicle-stimulating hormone, human chorionic gonadotropin, or the free beta-subunit of glycoprotein hormones is less than 0.001%.

Third and fourth generation assays provide the lower limit of detection needed to distinguish mildly subnormal TSH values (such as those seen in euthyroid hospital patients with a nonthyroidal illness) from the profoundly low values of frank hyperthyroidism. In addition, these assays appear to be helpful in subclassifying hyperthyroid patients according to the degree of TSH suppression, monitoring thyroid cancer patients on thyroxine who require complete suppression of TSH, and judging the adequacy of thyroid hormone replacement in hypothyroid patients.[82,191] However, not all chemiluminescent assays are capable of consistently achieving the detection limit of third generation assays.[194] Clinical laboratories should establish their own detection limit using human sera and clinically relevant patient samples.[173]

Specimen Collection and Storage

Serum or plasma is used for the measurement of TSH and the thyroid hormones, with serum free of hemolysis and lipemia preferred. Specimens are stable for 5 days at 2 °C to 8 °C and for at least 1 month when stored frozen. For newborn screening, whole blood is collected by heel puncture 48 to 72 hours after birth.

Reference Intervals

Secretion of TSH occurs in a circadian fashion: highest concentrations prevail at night between 0200 and 0400 hours, and lowest concentrations occur between 1700 and 1800 hours. Low-amplitude oscillations also occur throughout the day.[60] The nocturnal increase in TSH is lost in critical illness and after surgery. TSH surges immediately after birth, peaking at 30 minutes at 25 to 160 mIU/L; values decline back to cord blood concentrations by 3 days and reach adult values in the first weeks of life. There are no significant sex or race differences. Euthyroid serum TSH concentrations are log-Gaussian or log-normal in distribution; reference intervals should be evaluated logarithmically to achieve accurate estimates of the lower limit of normal.

Expected values using a third generation immunochemiluminometric assay are as follows:[209]

	mIU/L
Prematures, 28-36 wk (1st week of life)	0.7-27.0
Cord blood (>37 wk)	2.3-13.2
Children	
Birth to 4 days	1.0-39.0
2-20 wk	1.7-9.1
21 wk-20 yr	0.7-64.0
Adults	
21-54 yr	0.4-4.2
55-87 yr	0.5-8.9
Pregnancy	
First trimester	0.3-4.5
Second trimester	0.5-4.6
Third trimester	0.8-5.2

Determination of Thyroxine in Serum

Indirect Methods

Serum total T_4 concentrations were initially determined indirectly, using methods that measured the amount of iodine in a protein precipitate of serum (protein-bound iodine, PBI).[5] In addition to hormonal iodine, the PBI tests also measured iodoproteins, iodotyrosines, inorganic iodine, and thyroglobulin. More specific T_4 procedures involved the measurement of hormonal iodine in either a butanol extract of a serum protein precipitate (butanol-extractable iodine) or in a purified fraction of serum (T_4 by column).[128] These methods were useful because the iodine in T_4 normally accounts for 80% to 90% of all iodine in serum. Both butanol extraction and ion-exchange column chromatography selectively separate iodothyronines from other organic iodine compounds. Nevertheless, these methods were relatively nonspecific and rarely used. In some research centers, however, the PBI test is still used to assess patients with iodine-induced thyroid disease or thyroid dyshormonogenesis or as a method to diagnose thyroiditis.

Competitive Protein-Binding Assays

More sensitive and direct methods for the measurement of total serum T_4, known collectively as *competitive protein-binding assays*, were popular for many years.[146] These methods were based on the competition between labeled and unlabeled T_4 for a limited number of protein-binding sites. The specific binding protein used in the majority of these assays was TBG, which was usually obtained from pooled human sera. Anion-exchange resins were often used to separate free and bound hormone fractions. Competitive protein-binding methods, however, required a time-consuming step to extract T_4 from serum before the assay. Although these methods were free from interference by nonhormonal iodine, they were subsequently replaced by more sensitive and specific immunoassay methods.

Instrument-Based Methods

Electron capture gas chromatography,[157] high-performance liquid chromatography,[79] and isotope dilution tandem mass spectrometry[139,188A] have been used for measuring T_4 in human serum. The latter method has been suggested as a reference method for assay of T_4 in serum.[139] In this technique, tritium-labeled T_4 is added to a fixed amount of serum. T_4 is then extracted from the serum, derivatized, and subjected to combined gas chromatography–mass spectrometry.

Immunoassays

In general, most clinical laboratories assay total T_4 with competitive immunoassays performed on automated platforms. Many T_4 immunoassays use high-affinity antibodies produced against an albumin-T_4 conjugate. These polyclonal antisera are quite specific and are able to distinguish among molecules differing by only one atom (e.g., T_3 and T_4). Tg has sometimes been used as an immunogen, because it contains T_4 (and T_3) as part of its structure. Monoclonal antibodies against T_4 have also been developed.

Immunoassays of total T_4 measure both free and protein-bound thyroxine. Accurate measurement of total endogenous hormone therefore requires dissociation of T_4 from its serum transport proteins, because 99.97% of T_4 circulates tightly bound to TBG, albumin, and TBPA. Binding of T_4 to albumin is usually not a concern, because the association constant of T_4 for antibody (usually 10^9 L/mol or greater) is several orders of magnitude higher than that of T_4 for albumin (~1.6×10^6 L/mol). However, binding constants for T_4 with TBG and TBPA are high (2×10^{10} L/mol and 2×10^8 L/mol, respectively). Binding of T_4 to TBPA is overcome by

the use of barbital buffers, because barbital ions selectively inhibit this binding. Various blocking agents are used to inhibit binding of T_4 to TBG with 8-anilino-1-naphthalene-sulfonic (ANS) acid being the agent of choice, although salicylate, thimerosal (Merthiolate), and phenytoin are also used. These blocking agents effectively displace T_4 from TBG without affecting its binding characteristics with antibody. In some assays, proportional bias has been attributed to incomplete release of T_4 from serum binding proteins.[150]

Isotopic Methods

Radioactive iodine (e.g., ^{125}I) has been widely used as a signal to follow and measure the distribution of T_4 between unbound and antibody-bound fractions. Before the advent of nonisotopic assays, many reliable commercial RIA kits were used. These RIA kits differed primarily in their approach to separation of free and bound labeled T_4 fractions. Some separation methods used protein precipitation with ammonium sulfate or polyethylene glycol. Others used a double-antibody technique with polyethylene glycol to hasten and enhance separation. A majority, however, used a solid-phase technique with T_4-specific antibody chemically or physically bound to beads, magnetizable particles, or tubes. The latter two modes simplified the procedure by eliminating the centrifugation step for separation of bound and free labeled components.

The older RIA kit procedures required about 1 hour incubation either at room temperature or at 37 °C. Overall, a batch of 20 patient specimens, 2 or 3 controls, and 6 calibrators (each in duplicate) required less than 3 hours to process. Sample volumes per test were small (about 25 μL). Interassay reproducibility, expressed as a coefficient of variation, was typically ±7% at a T_4 concentration of 3.8 μg/dL (50 nmol/L); cross-reactivity of T_3 was about 5% at the 50% displacement concentration. The detection limit of these assays (defined as mean minus 2 standard deviations [SD] of the zero calibrator) was approximately 0.4 μg/dL (5 nmol/L). This limit of detection was not sufficient to measure T_4 directly in dialysates or ultrafiltrates of serum. Highly sensitive T_4 RIAs that have a detection limit of 0.8 pg per tube or 0.16 ng/dL of dialysate were eventually developed.

Nonisotopic Methods

Considerable effort was expended in the development of alternative technologies that did not require the use and measurement of radioactivity. A number of nonisotopic assays for T_4 were subsequently developed commercially for use on fully automated immunoassay systems or for use with existing chemistry analyzers. According to a 2002 College of American Pathologists Ligand Assay Survey,[29] more than 95% of laboratories now use a nonisotopic T_4 method. A variety of different labels were used to construct these nonisotopic assays. Enzymes such as horseradish peroxidase, alkaline phosphatase, and β-D-galactosidase were the most widely used in conjunction with fluorescent and chemiluminescence-based molecules.

Enzyme immunoassays that require physical separation of free and bound T_4 are generally based on principles analogous to those of conventional RIAs except that enzyme activity rather than radioactivity is measured. Most enzyme immunoassays use labeled T_4 as antigen. An assortment of photometric, fluorescent, and luminescent substrates have been used to monitor the enzyme activity of the antibody-bound fraction.

Like radioassays, heterogeneous enzyme assays for T_4 make extensive use of solid-phase separation systems. Some methods immobilize the T_4 antibody on plastic surfaces (e.g., polystyrene beads, test tubes, and microwells) so that bound and free analyte are conveniently separated by decanting and washing. For example, one automated assay uses test tubes that contain polystyrene beads coated with a monoclonal T_4 capture antibody.[2] T_4 in the specimen, liberated from binding proteins by ANS, competes with a T_4–alkaline phosphatase conjugate for a limited number of binding sites on the bead. After washing off the unbound label, the catalytic activity of the bound enzyme is estimated using a chemiluminescent substrate (adamantyl dioxetane phenylphosphate ester). This combination of an enzyme label and a chemiluminescent end point has been applied to other automated T_4 procedures.[70,178] An antibody-coated tube enzyme immunoassay has also been used with T_4 using a peroxidase-T_4 conjugate and a photometric substrate.[206]

Several enzyme immunoassays attach T_4 antibodies to ferromagnetic particles so that free and bound T_4 can be separated magnetically. For example, one fully automated enzyme immunoassay system uses plastic cups that contain magnetic beads coated with a specific T_4 antibody.[212] Endogenous T_4, displaced from its binding proteins by ANS, competes with T_4 labeled with alkaline phosphatase for a limited number of binding sites on the immobilized antibody. The magnetized beads are washed to remove unbound enzyme-labeled T_4 and are then incubated with a fluorogenic substrate. The amount of enzyme-labeled T_4 that binds to the beads is inversely proportional to the T_4 concentration in the test specimen.

Homogeneous enzyme immunoassays have also been developed for serum T_4 determination. These procedures are rapid and simple to use and have also been applied to several major automated instruments.[107] For example, the enzyme-multiplied immunoassay technique (EMIT) for T_4 measurement uses glucose-6-phosphate dehydrogenase covalently linked to T_4 as the enzyme label.[124] Binding of T_4-specific antibody to this label reduces enzyme activity, perhaps as a result of steric or allosteric inhibition As the concentration of unlabeled T_4 increases, less enzyme-labeled hormone is bound by the antibody. As a result, the catalytic activity of the unbound enzyme conjugate increases in direct proportion to the amount of T_4 in the specimen. The indicator reaction involves oxidation of glucose-6-phosphate with simultaneous reduction of nicotinamide-adenine dinu-

cleotide (oxidized form; NAD+) to nicotinamide-adenine dinucleotide (reduced form; NADH). The rate of increase of absorbance at 340 nm is related to T_4 concentration by means of a calibration curve. Separation of free from antibody-bound labeled hormone is not required in this assay, because the latter is inactive.

The cloned enzyme donor immunoassay (CEDIA) technique for T_4 measurement is based on the use of inactive fragments of β-galactosidase called *enzyme acceptor* (EA) and *enzyme donor* (ED).[83] In this method, T_4 in a serum sample competes with ED-labeled T_4 for a limited number of anti-T_4 binding sites. As the concentration of unlabeled T_4 increases, less ED-labeled T_4 binds to the antibody and more reassociates with EA to form an active enzyme. The catalytic activity of the holoenzyme increases in proportion to the amount of T_4 in the sample. This method has been adapted for use on on routine chemistry analyzers.[31]

Fluorescent probes are an attractive alternative to the use of radiolabels, especially because additional substrates are not required to monitor changes in fluorescence. Both heterogeneous (separation required) and homogeneous (nonseparation) fluorescence methods have been described for the measurement of T_4 in serum. An example of the latter is the very popular fluorescence polarization immunoassay.[19,179] In this automated system, fluorescein-labeled T_4 and T_4 in patient specimens compete for binding sites on a T_4 antibody. Polarized excitation light (485 nm) is used to induce fluorescence of the tracer. The emitted light (525 to 550 nm) is also polarized, but the degree of polarization is inversely related to the rate of rotation of the tracer in solution. Polarization of fluorescence of the tracer is therefore very dependent on its effective size. For tracer bound to antibody, the polarization is higher, because the complex is hundreds of times larger than the free tracer. Thus the observed polarization is inversely proportional to the concentration of T_4 present in the specimen. Interassay precision, expressed as a coefficient of variation, is 6% at a T_4 concentration of 4.0 μg/dL (52 nmol/L); cross-reactivity of T_3 is less than 10%. The detection limit, defined as mean minus 2 SD of the zero calibrator, is approximately 1.9 μg/dL (25 nmol/L). Unlike RIA methods, in which each batch of patient specimens required two or three controls and six calibrators (each in duplicate), the fluorescence polarization method needs only a single sample of control tested once every 24 hours each day of use. Once a T_4 calibration is stored, samples may be tested without further calibration unless a new lot of reagent is used.

Heterogeneous fluorescent immunoassays for T_4 based on lanthanide rare earth ions and time-resolved fluorescence were also developed.[43] The use of europium chelates as fluorescent probes is particularly attractive because of their extraordinarily long Stoke's shifts and long fluorescence decay times. Thus the sharp emission peak of europium (613 nm) can be easily separated from scattering caused by excitation light (340 nm) or by interfering substances in serum (400 to 600 nm). In a typical assay, T_4 present in serum specimens competes with europium-labeled T_4 for a limited number of binding sites on T_4-specific monoclonal antibodies. Separation of antibody-bound and free antigen is effected by using a second antibody directed against mouse immunoglobulin G that is coated to the surface of microwells. After incubation and washing, the europium ions are dissociated from the bound phase, converted into a highly fluorescent chelate, and measured in a specially designed fluorometer with time-resolution capability. The fluorescence signal is inversely proportional to the amount of T_4 in the specimen. Because counting times for each specimen are extremely short, a rapid throughput of specimens is allowed. An interesting variant of this technique involves the attachment of biotin to a monoclonal T_4 antibody and streptavidin coupled to a europium chelate.

The feasibility and advantages of using chemiluminescence molecules as direct labels for T_4 immunoassays were subsequently recognized, and fully-automated, random-access analyzers using this signaling system are now widely used to measure total and FT_4 by immunoassay. In one system,[119] endogenous T_4 competes with T_4 coupled to paramagnetic particles for binding with a mouse monoclonal antibody labeled with acridinium ester. After a brief incubation, the magnetized particles are washed to remove the unbound label; the bound fraction is then quantitated in a luminometer after the addition of hydrogen peroxide to initiate the chemiluminescence reaction.

A different immunoassay for T_4 uses electrochemiluminescence as the detection system.[46] This technology uses a ruthenium tris(bipyridyl) complex as the reporter molecule, which, in the presence of tripropylamine, participates in an electrochemiluminescent reaction that is triggered by the application of an electrical potential at two electrodes. Serum T_4, which is set free by ANS, competes with biotin-labeled T_4 for a $Ru(bpy)_3^{2+}$-labeled anti-T_4 polyclonal antibody. The complex of labeled antibody and biotinylated T_4 is captured by streptavidin-coated paramagnetic particles. The reaction mixture is then drawn into a flow cell where the particles are fixed to an electrode surface by application of a magnetic field. A voltage is applied, and the resulting electroluminescence is measured. This automated system requires only 15 μL of sample; interassay precision, expressed as coefficient of variation, is generally found to be ±3% to 6% in the clinical range. Calibration is performed using two calibrators, and the onboard stability of reagents is 4 weeks.

Particle-enhanced immunoassays involving turbidimetric measurements have been described for T_4 in serum. These homogeneous assays are based on competition between the T_4 in the sample and a T_4-ficoll conjugate for binding sites on a specific monoclonal antibody coupled to microparticles. The rate of agglutination is determined turbidimetrically by measuring the absorbance change at 600 nm. Automated systems using this method have been developed.[73]

Dry-chemistry immunoassay systems that require no liquid reagents and no sample pretreatment have also been developed for T_4.[35,155] One system uses a thin-film multilayer test module consisting of three distinct layers coated on a plastic base. The serum specimen first spreads through a topcoat layer, which contains an agent (phenoxy naphthalene sulfonic acid) to displace T_4 from its binding proteins. The unbound T_4 then passes through an iron oxide screen layer into a signal layer, where the hormone competes with and displaces rhodamine-labeled T_4 from the binding sites of an immobilized T_4 antibody. The unbound fluorescent-labeled T_4 diffuses into the opaque screening layers above, where it cannot be seen by the optical detection system. The fluorescent signal of the antibody-bound fraction is measured by front-surface fluorimetry and is inversely proportional to the concentration of T_4 in the serum specimen.

Specimen Collection and Storage

Serum is the preferred specimen for the measurement of T_4; plasma with ethylenediaminetetraacetic acid (EDTA) or heparin as anticoagulant is also used. However, plasma tends to form fibrin clots after freezing and thawing; these clots may interfere mechanically with an assay, especially in an automated system. Gel barrier tubes have no apparent adverse effect on T_4 concentrations. T_4 in serum is quite stable; storage of serum specimens at room temperature up to 7 days shows no appreciable loss of T_4. However, serum specimens are best stored at 2 °C to 8 °C if they will not be tested within 24 hours. If longer periods of storage are necessary, freezing the specimens is recommended. Frozen specimens are stable for at least 30 days. Repeated freezing and thawing of the specimens should be avoided. Hemolysis and lipemia have no significant effect on most T_4 immunoassays; however, grossly hemolyzed specimens should be avoided, because hemolysis may dilute the sample and cause a false decrease in the T_4 concentration. Turbid samples should be centrifuged before testing. Immunoassay procedures are not affected by organic dyes and inorganic iodine compounds. However, radioactive materials can interfere with RIA methods. Patients undergoing therapy for a thyroid disorder should stop treatment 1 month before sampling if a true baseline is to be established. T_4 autoantibodies interfere with some immunoassays for T_4 in that they can produce artificially low or high results, depending on the method.[218]

Specimens have been obtained from infants by heel puncture; such specimens also are collected in capillary tubes or on filter paper. Dried blood specimens are stable and easily transported and are ordinarily obtained for purposes of screening neonates for congenital hypothyroidism.[135A] When this collection technique is used, a one-eighth-inch dot is punched out from the blood-saturated paper and is extracted into the buffer before performing the T_4 assay. It is best to avoid touching the filter paper or exposing it to extreme heat or light.

Reference Intervals[209]

	µg/dL	nmol/L
Cord	7.4-13.0	95-168
Children		
1-3 days	11.8-22.6	152-292
1-2 wk	9.8-16.6	126-214
1-4 mo	7.2-14.4	93-186
4-12 mo	7.8-16.5	101-213
1-5 yr	7.3-15.0	94-194
5-10 yr	6.4-13.3	83-172
10-15 yr	5.6-11.7	72-151
Adults (15-60 yr)		
Males	4.6-10.5	59-135
Females	5.5-11.0	65-138
Adults >60 yr	5.0-10.7	65-138
Newborn screen (whole blood)		
1-5 days	>7.5	>97
6 days	>6.5	>84

Comments

By itself, the concentration of total T_4 does not provide adequate clinical information; an FT_4E test should be determined along with the total T_4 measurement to compensate for binding protein effects. Cord blood T_4 concentrations are lower in preterm than in full-term neonates, and they correlate positively with birth weight in full-term infants. At birth, serum total T_4 concentrations are higher in neonates because of the maternal estrogen-induced increase in serum TBG; FT_4 values are near adult concentrations. Total T_4 values rise abruptly in the first few hours after birth and decline gradually until the age of 15. Males experience a gradual decline in T_4 production as they mature sexually; females do not.

Reference intervals for newborns should be developed by each laboratory that provides screening for neonatal hypothyroidism. Imprecision of the T_4 assay is handled on a daily basis, usually by setting floating cutoffs to include false-positive results and to preclude false-negative results.[94]

Based on biological information, analytical performance goals have been recommended for thyroid hormone assays.[173] When a total T_4 assay is used to rule in or rule out disease, the suggested goals for maximum bias and imprecision (calculated as a percent coefficient of variation) are ±2.9% and ±5.7%, respectively. When the assay is used for monitoring changes in an individual over time, bias and imprecision goals are ±1.3% and ±2.6%, respectively.

Determination of Triiodothyronine in Serum

Older Methods

T_3 has been measured using a variety of chemical reactions, but such chemical methods are generally too insensitive or impractical for measuring the low T_3 concentrations present

in serum. In the 1960s, competitive protein-binding assays were introduced for the measurement of T_3, with TBG serving as a natural binding protein; prior isolation of T_3 from serum (e.g., by extraction of iodothyronines with a cation-exchange resin, followed by separation of T_3 and T_4 using paper chromatography) was required to increase assay performance.[198]

Immunoassay

Direct measurement of T_3 by immunoassay has been made possible by the production of T_3-specific antibodies. Unlike T_4 antiserum, high-titer, specific T_3-antiserum is seldom obtained by immunization of rabbits with naturally occurring Tg. Good-quality antiserum, however, has been produced using T_3-enriched Tg, T_3-human serum albumin (HSA), or T_3-bovine serum albumin (BSA) conjugates.[23] Monoclonal T_3 antibodies have also been produced using hybridoma technologies.

Isotopic Methods

Numerous commercial kits have been introduced for measuring serum total T_3 concentrations. Procedures are similar to those described for T_4 except that an ^{125}I-T_3 tracer and T_3-specific antibody are used. Liquid-phase separation systems, such as those using charcoal adsorption, polyethylene glycol, and double-antibody precipitation, are not used as often as solid-phase systems (e.g., those using antibody-coated tubes or magnetizable particles). As with the T_4 methods, ANS is frequently used to release T_3 from its serum binding proteins without disturbing the binding of T_3 to antibody. A typical calibration curve ranges from 25 to 800 ng/dL; values for unknown specimens are obtained from the curve by interpolation.

Nonisotopic Methods

Nonisotopic assays similar to those described for serum T_4 have been applied to the measurement of T_3. Many of these procedures have been developed for use on fully automated immunoassay systems,[97] and some are compatible with chemistry analyzers. Many commercial methods use peroxidase or alkaline phosphatase to label T_3 antigens or T_3 antibodies; enzyme activity is commonly determined using a variety of sensitive photometric,[105,120] fluorescent,[3,142] or chemiluminescent[36] substrates. Immunoassays for T_3 that use fluorescent[156] and chemiluminescent labels[30] are also available and, as with T_4 assays, chemiluminescence-based assays on automated platforms have become the rule rather than the exception. Both heterogeneous (separation required) and homogeneous methods have been described.[98,166] An example of the former is the microparticle enzyme immunoassay for T_3.[74] In this automated system, serum T_3 binds to anti–T_3-coated microparticles, forming an antibody-antigen complex that is then separated by a glass-fiber matrix. An alkaline phosphatase–labeled T_3 conjugate, which forms a sandwich with the T_3 bound to the glass fiber, is added. A fluorescent product is formed when the enzyme substrate, 4-methylumbelliferyl phosphate, reacts with the enzyme label. Values obtained with this enzyme immunoassay are generally higher than those obtained with RIA methods.

Specimen Collection and Storage

Serum is the preferred specimen; plasma with EDTA or heparin as anticoagulant may also be used. However, gel tubes should be avoided for T_3 measurements due to possible contaminating chemicals in the gel that can cause a false elevation in results. Serum specimens once collected are best stored at 2 °C to 8 °C if they will not be tested within 24 hours. If longer periods of storage are necessary, freezing the specimens is recommended. Frozen specimens are stable for at least 30 days. Repeated freezing and thawing of the specimens should be avoided. Turbid samples should be centrifuged before testing. Specimen volume per test is usually 50 to 100 µL.

Reference Intervals

The reference intervals for T_3 may vary from one procedure and reference population to another. Each laboratory should establish its own reference intervals. Expected values using an RIA method are as follows.[209]

	ng/dL	nmol/L
Cord (>37 wk)	5-141	0.08-2.17
Children		
1-3 days	100-740	1.54-11.40
1-11 mo	105-245	1.62-3.77
1-5 yr	105-269	1.62-4.14
6-10 yr	94-241	1.45-3.71
11-15 yr	82-213	1.26-3.28
Adolescents		
16-20 yr	80-210	1.23-3.23
Adults		
20-50 yr	70-204	1.08-3.14
50-90 yr	40-181	0.62-2.79
Pregnancy[33]		
First trimester	81-190	1.25-2.93
Second and third trimesters	100-260	1.54-4.00

Comments

Different T_3 immunoassays may show unexplained discrepancies between values for the same sera. Results from interlaboratory quality assurance schemes also demonstrate a higher analytical variance for T_3 than for T_4 methods. Many factors have been suggested as accounting for these disparities, such as the lower quantity of T_3 in sera, differences in antisera cross-reactivity, protein interferences, and different assay limits of detection.[223]

Typical coefficients of variation for interassay performance are ±5% to 7%; assay detection limit is approximately 10 ng/dL. Most T_3 immunoassays have negligible cross-reac-

tivity with T_4 (<0.12%), thus permitting direct measurement of T_3 in serum specimens regardless of the fact that T_3 concentrations are 100-fold lower than are T_4 concentrations. T_3 autoantibodies interfere with some assays, producing low or high results (depending on the method).

Performance goals for bias and precision have been suggested for T_3.[173] When a total T_3 assay is used for diagnostic applications, the suggested goals for maximum bias and imprecision (expressed as percent coefficient of variation) are ±5.7% and 11.5%, respectively. When the assay is used for therapeutic applications, bias and imprecision goals are ±2.6% and 5.2%, respectively. The major clinical roles for total T_3 measurements are in the diagnosis and monitoring of hyperthyroid patients with suppressed TSH and normal FT_4 concentrations ("T_3-thyrotoxicosis"); T_3 measurements have only a limited role in euthyroid and hypothyroid patients.[102]

Determination of Reverse Triiodothyronine (rT_3) Using Radioimmunoassay

The rT_3 molecule (3,5,5′ triiodothyronine) is biologically inert. A number of radioimmunoassay methods for rT_3 measurement have been published.[65] Antisera for rT_3 are generally obtained by immunizing rabbits using rT_3 conjugates with HSA or BSA.[22] The antisera are usually devoid of significant cross-reactivity with T_2 or T_3; cross-reaction with T_4 varies between 0.01 and 0.15%.[136] Like T_3 and T_4, rT_3 also binds with TBG, TBPA, and albumin in serum. The binding of rT_3 to serum proteins has been overcome by the use of an ethanol extract of serum or by the addition of ANS to the serum in a manner similar to that described for T_3 and T_4.[24] Separation of free and antibody-bound hormone is often achieved using a second antibody (e.g., anti-rabbit γ-globulin) procedure with precipitation accelerated with polyethylene glycol.

Although commercial assays for direct serum analysis of rT_3 are available, kit procedures are not as convenient as are those for other thyroid hormones and no rT_3 method has been adapted to an automated platform because this measurement has no recognized diagnostic value. In comparison with the reference method described by Chopra,[22] the typical kit procedure is relatively fast; it requires a 3-hour incubation at room temperature, followed by polyethylene glycol precipitation and centrifugation. The entire procedure requires less than 6 hours to perform.

Specimen Collection and Storage

Serum is the preferred specimen; plasma with EDTA or heparin as anticoagulant may also be used. Serum specimens are best stored at 2 °C to 8 °C if they will not be tested within 24 hours. If longer periods of storage are necessary, freezing the specimens is recommended. Frozen specimens are stable for at least 30 days. Repeated freezing and thawing of the specimens should be avoided. Turbid samples should be centrifuged before testing. Amniotic fluid obtained by amniocentesis or by transmembrane aspiration at delivery may also be analyzed for rT_3. The amniotic fluid should be clear. To avoid debris and other cellular particles, centrifugation of the fluid for 15 minutes at 900 ×g is suggested. Specimens are stable for 1day at 2 °C to 8 °C and for up to 3 months when frozen. Amniotic fluid contaminated with hemolyzed blood should not be used.

Reference Intervals [209]

	ng/dL	nmol/L
Cord blood (>37 wk)	130-300	2.00-4.62
Children		
1 day	83-194	1.28-2.99
2 days	107-209	1.65-3.22
3 days	102-166	1.57-2.56
1 mo-20 yr	10-35	0.15-0.54
Adult	10-28	0.15-0.43
Maternal serum (15-40 wk)[209]	11-33	0.17-0.51
Amniotic fluid (17-22 wk)[209]	163-599	2.51-9.22

Comments

Reverse T_3 in serum is present almost entirely as a result of its generation from T_4 in peripheral tissues by 5-deiodinases. The concentration of serum rT_3 is lower than that of T_3 because of the faster metabolic clearance of rT_3. Serum rT_3 concentrations are elevated at birth, but decrease to stable values by about the fifth day of life. Reverse T_3 in amniotic fluid decreases with increasing gestational age. The use of reverse T_3 in patients with the euthyroid sick syndrome has fallen out of favor with the recognition that rT_3 is not always elevated in illness. Specifically, renal failure is associated with low rT_3 concentrations.

Determination of Free Thyroid Hormones

T_4 and T_3 circulate in the blood as equilibrium mixtures of free and protein-bound hormones. Thus changes in the concentration or affinity of TBG or other transport proteins profoundly affect the total hormone concentration in serum. Alternatively the steady-state concentration of the free hormone is independent of these binding protein variations and remains almost constant.

The interaction between free thyroid hormones and their binding proteins (TBPs) conforms to a reversible binding equilibrium that is described by the following mass action relationship:

$$[FT_4] \times [TBP] = K \times [T_4{:}TBP]$$

where

$[FT_4]$ = concentration of free T_4 in serum
$[TBP]$ = concentration of unoccupied binding sites on TBP
K = association constant
$[T_4{:}TBP]$ = concentration of T_4-occupied binding sites on TBP

The relationship among these entities has important diagnostic implications. A primary increase in either [FT_4] or [TBP] drives this reaction to the right, increasing serum [T_4:TBP]. Because 99.97% of the total T_4 is bound to TBP, the value of [T_4:TBP] is considered equivalent to that of total T_4. Hyperthyroidism produces a primary increase in FT_4, whereas estrogens and idiopathic or genetic conditions may produce a primary increase in TBP. In both cases, [T_4:TBP] increases, but in the former, the patient is ill and requires treatment; in the latter, the patient is euthyroid. Likewise a low serum [T_4:TBP] may be due to a primary decrease in [FT_4] or to a primary decrease in [TBP]. It is therefore clinically important to differentiate between changes in [T_4:TBP] that are due to primary changes in [FT_4] (e.g., hyperthyroidism or hypothyroidism) and those that are due to primary changes in [TBP].

Numerous methods have been developed for assessing the concentrations of FT_4 and FT_3 in serum. These methods include direct assays that currently serve as reference methods and indirect assays that are more widely available for general laboratory use. The following section describes the principles of these methods and offers some guidelines for their use. The theoretical basis, analytical validity, and clinical utility of these methods have been discussed.[47,48,50] Special reports from the Nomenclature Committee of the American Thyroid Association,[80] the National Academy of Clinical Biochemistry,[173] and the NCCLS also review some of the issues and concerns regarding free thyroid hormone measurements.

Direct Reference Methods

Direct measurement of FT_4 and FT_3 in serum presents a considerable technical challenge as free hormone concentrations are exceedingly low in normal serum. For example, they are approximately 0.03% of the total serum T_4 and 0.3% of the total serum T_3 concentrations, respectively. Consequently assays for them must be capable of measuring subpicomole amounts. Theoretically the most reliable methods for measuring FT_4 and FT_3 in serum employ equilibrium dialysis and ultrafiltration techniques that physically separate free hormone from protein-bound hormone before direct measurement of the free fraction with a sensitive T_4 or T_3 immunoassay. Only minimal dilution of serum specimens is allowed, because dilution alters the binding of drugs, free fatty acids, and other substances to serum proteins, thus disturbing the equilibrium between bound and free hormone.

Historically, direct procedures were too cumbersome, time-consuming, and expensive for use in a routine clinical laboratory. The introduction of very sensitive immunoassays for T_4 and T_3 combined with improvements in the dialysis or ultrafiltration of undiluted serum has allowed direct measurement of free thyroid hormones. Thus *direct equilibrium dialysis* and *ultrafiltration* methods are available for FT_4 measurement.[149,210]

Principles

Direct Equilibrium Dialysis. In this method, undiluted serum specimens are dialyzed for 16 to 18 hours at 37 °C in a reusable dialysis chamber.[149] The dialysis buffer provides for minimal changes in the serum matrix. The dialysate is then analyzed directly using a sensitive RIA. The range of reportability is 2 to 128 ng/L (2.6 to 165 pmol/L), and the interassay coefficient of variation is approximately ±7%.

Ultrafiltration. The second method is an ultrafiltration procedure for FT_4 determination in serum that is significantly less time-consuming than dialysis.[210] In this method, the serum specimen is adjusted to pH 7.4, incubated for 20 minutes at 37 °C (to achieve equilibrium of the binding at this temperature), and then applied to an ultrafiltration device for centrifugation for 30 minutes at 37 °C and 2000 ×g (using a fixed-angle rotor). Subsequently the ultrafiltrate is analyzed for T_4. Variable protein leakage in ultrafiltration devices continues to hamper commercialization of this method.

Specimen Collection and Storage

Serum is the preferred specimen; plasma with EDTA or heparin as anticoagulant may also be used. Serum specimens are best stored at 2 °C to 8 °C if they will not be tested within 24 hours. If longer periods of storage are necessary, freezing the specimens is recommended. Frozen specimens are stable for at least 30 days. Repeated freezing and thawing of the specimens should be avoided. Turbid samples should be centrifuged before testing.

Reference Intervals

Expected values for FT_4 using direct equilibrium dialysis are as follows:[209]

	ng/dL	pmol/L
Newborns (1-4 days)	2.2-5.3	28.4-68.4
Children (2 wk-20 yr)	0.8-2.0	10.3-25.8
Adults (21-87 yr)	0.8-2.7	10.3-34.7
Pregnancy		
First trimester	0.7-2.0	9.0-25.7
Second and third trimesters	0.5-1.6	6.4-20.6

Comments

FT_4 assays based on direct equilibrium dialysis or ultrafiltration measure free hormone without the need for total hormone measurements. These methods are unaffected by either variations in serum binding proteins or thyroid hormone autoantibodies. However, IV heparin administration can cause spurious elevations in FT_4 determined by these techniques as a consequence of in vitro generation of free fatty acids. Mean values obtained in euthyroid healthy subjects are reported to be slightly higher when using ultrafiltration methods than when using equilibrium dialysis.[210,222]

Analytical performance goals have been recommended for free thyroid hormone assays.[102,150,173] When an FT_4 assay

is used to rule in or rule out disease, the suggested goals for maximum bias and imprecision (calculated as percent coefficient of variation) are ±3.8% and 7.7%, respectively. When the assay is used for monitoring changes in an individual over time, bias and imprecision goals are ±2.4% and ±4.8%, respectively.

Indirect Methods for Estimating Free Thyroid Hormones

Most routine immunoassay methods for determining FT_4 and FT_3 concentrations in serum are estimates. These approaches are often more convenient and less expensive than reference methods, and most are available commercially in kit form and on automated immunoassay instruments. Two test strategies are used for estimating the concentrations of free hormones: "indirect" index methods and "direct" immunoassays.

Unlike direct reference assays, indirect index methods use two separate tests to estimate the free hormone concentration: a total serum T_4 (or T_3) measurement and an assessment of either the serum TBG concentration or the fraction of T_4 (or T_3) that is free in serum; the latter is traditionally derived using equilibrium tracer dialysis or "T uptake" methods. Results of these tests are then combined mathematically to give estimates of the free hormone concentration. Indirect index-based methods have essentially fallen out of favor in deference to the direct immunoassay methods.

Direct two-step and one-step immunoassays estimate free hormone concentrations by using antibody extraction techniques. Although it is often claimed or implied that these immunoextraction assays measure FT_4 or FT_3 directly, virtually all methods do so indirectly by relating test results to extracted serum calibrators with free hormone values that have been independently measured using reference methods (e.g., direct equilibrium dialysis/RIA). Further, studies have shown that all of the free hormone estimate methods on current instrument platforms are binding protein dependent to some extent.[217A]

Free Hormone Fraction by Indirect Equilibrium Tracer Dialysis

Several isotopic methods have been used to accurately estimate the free hormone fraction, including equilibrium tracer dialysis,[90,199] ultrafiltration,[189] Sephadex chromatography,[188] and polyacrylamide gel filtration.[134] However, these techniques are very cumbersome and time consuming for routine clinical use and, with the exception of equilibrium tracer dialysis, have found little practical application. Unfortunately the free hormone fraction as estimated in normal sera by equilibrium tracer dialysis varies substantially among laboratories. Methodological difficulties include the presence of residual impurities in the tracer, the temperature and duration of dialysis, the adsorption of tracer by components of the dialysis system, and the in vitro generation of free fatty acids.[80]

Principle. Test serum is enriched with very small quantities of radioiodine-labeled T_4, which quickly distributes between free and bound T_4 to approximate the distribution of endogenous hormone. The fraction of labeled hormone that dialyzes through a semipermeable membrane is then measured. The method of Ingbar and coworkers[90] consists of a double dialysis procedure. In the first dialysis, the serum-radioactive T_4 mixture is dialyzed against phosphate buffer (pH 7.4) overnight at 37 °C. The dialysate (i.e., the part that passes through the semipermeable membrane) contains both free radiolabeled thyroxine and labeled inorganic iodide and other contaminating iodinated compounds generally present in commercial preparations of radioiodine-labeled T_4. The second dialysis is used to remove these contaminants. In this procedure, a mixture of the first dialysate and pooled plasma is dialyzed against phosphate buffer containing an anion exchange resin. The resin adsorbs only the radioactive contaminants and thereby maintains an effective diffusion gradient for impurities until all are removed. Because the binding proteins in the pooled plasma possess a high affinity for T_4, little if any radioactive T_4 is available for diffusion and adsorption by the resin. All radioactivity that remains within the dialysis bag is considered to be the FT_4.

The method of Sterling and Brenner[199] simplified the FT_4 method significantly by replacing the second dialysis step with a precipitation procedure. It involves dialysis of the serum-radioactive T_4 mixture against phosphate buffer as described previously and precipitation of the radioactive T_4 in the dialysate with magnesium chloride after addition of carrier T_4. This method is often called the *magnesium precipitation method,* and the method of Ingbar and coworkers[90] is called the *resin dialysis technique.* Values of % FT_4 are calculated according to the following formula:

$$\%\,FT_4 = \frac{C_o}{C_i} \times 100$$

where C_o is the counts per minute of dialysate-magnesium precipitate, and C_i is the counts per minute per milliliter of dialysate.

Specimen Collection and Storage. Serum is the preferred specimen; plasma with EDTA or heparin as anticoagulant may also be used. Serum specimens are best stored at 2 °C to 8 °C if they will not be tested within 24 hours. If longer periods of storage are necessary, freezing the specimens is recommended. Frozen specimens are stable for at least 30 days. Repeated freezing and thawing of the specimens should be avoided. Turbid samples should be centrifuged before testing.

Reference Intervals. Reference values for % FT_4 range between 0.02% and 0.04% of total hormone concentration. Because T_3 is less firmly bound by TBG than is T_4, the dialyzable fraction of T_3 is appreciably greater (by almost 10 times) than that of T_4. Thus the reference interval for % FT_3 is 0.2% to 0.4%.

Calculation of Free Hormone Estimates

Principle. The free hormone fraction, as measured by dialysis or ultrafiltration of diluted serum containing tracer

T_4 or T_3, is multiplied by the respective total hormone concentration to obtain indirect estimates of FT_4 or FT_3:

$$FT_4E = \text{Total } T_4 \times \%\, FT_4$$
$$FT_3E = \text{Total } T_3 \times \%\, FT_3$$

Reference Intervals. The expected calculated values for FT_4 and FT_3 using equilibrium tracer dialysis are as follows:

FT_4E[52]

	ng/dL	pmol/L
Cord	1.7-4.0	22-52
Newborn	2.6-6.3	34-81
Adult	0.8-2.3	10-30

FT_3E[33]

	pg/dL	pmol/L
Cord	15-391	0.2-6.0
Child and adult	210-440	3.2-6.8
Pregnancy	200-380	3.1-5.9

Free Hormone Fraction by Uptake Methods (Thyroid Hormone–Binding Ratio)

The THBR is derived from a version of the T_3 or T_4 uptake test. Uptake tests are used to estimate the number of unoccupied (unsaturated) thyroid hormone binding sites on serum proteins. This information is important because variations in total thyroid hormone concentrations in blood, as discussed previously, have resulted from changes in binding protein concentrations. Values obtained by uptake methods are expressed as a THBR, which is directly proportional to the free hormone fraction (within limits). Measurement of THBR, in conjunction with a total hormone concentration, is a clinically useful indirect method for calculating the FT_4 (or FT_3) index. The index approach is particularly useful in patients with nonthyroidal illness in whom FT_4 immunoassay methodologies are unreliable. Specifically, TT_4 measurement is more diagnostically useful in such patients provided that values are interpreted in accord with the severity of illness in the patient that is indirectly reflected by abnormalities in THBR.

Isotopic Methods

Many different radioactive tracer methods have been used for estimating the unsaturated thyroid hormone binding capacity. The simplest is the T_3 *uptake test.* Traditionally, this test is performed by measuring the distribution of radiolabeled T_3 between serum binding proteins and a solid-phase binding material. In a typical assay, a diluted sample of patient serum is allowed to equilibrate with a trace amount of ^{125}I-T_3 and the secondary binder. A portion of the radioactive T_3 binds to empty binding sites on serum proteins, principally TBG, and the remainder attaches to the solid matrix. At the end of a specific incubation period, the reactants are separated, and the proportion of radioactivity bound by the solid matrix (the "uptake") is measured. The amount of T_3 tracer bound to the secondary binder varies inversely with the number of unoccupied TBG binding sites in the serum specimen and directly with the free fraction of T_4 and T_3.

In the original T_3 uptake test, red blood cells were used to remove labeled hormone not tightly bound to TBG.[76] To minimize methodological difficulties, erythrocytes were replaced with an ion-exchange resin, either in granular form or impregnated in a sponge.[28] The test then became known as the *resin* T_3 uptake test. Many solid-phase materials have subsequently been used, including charcoal, talc, macroaggregated albumin, or immobilized T_3 antibody. Many of these secondary binders are incorporated in commercial kit methods.

Radiolabeled T_3 is used more often than is labeled T_4 because of its relatively low affinity for TBG compared with T_4, which leads to higher uptake values and better discrimination between normal and abnormal test results. In addition, radioactive T_3 fills the unoccupied binding sites on TBG but does not displace any bound T_4. Under most circumstances, the use of labeled T_3 to approximate the free fraction of T_4 does not introduce serious errors, because T_3 and T_4 are both predominantly bound by TBG and occupy virtually the same binding sites. Major problems are encountered, however, when some factor changes the binding affinity for T_4 but not for T_3. For example, in abnormal binding protein states (i.e., NTI) differential abnormalities in protein binding of T_3 versus T_4 may occur, rendering a T_3 uptake an inappropriate approach for calculating an FT_4I.

T_3 uptake values are customarily expressed as matrix-bound counts divided by the total counts added (typical euthyroid reference interval: 25% to 37%). This calculation, however, is theoretically unsound and has led to problems of interpretation, particularly when serum TBG concentrations are very high or very low. Instead the uptake value should be expressed as the matrix-bound counts divided by the counts that remain bound to serum proteins (typical euthyroid reference interval: 33% to 50%). This result corresponds more closely to the mass action law and is more linearly related to the free hormone fraction over a wide range of values.

Several uptake kits are commercially available. T_3 uptake values for individual subjects depend on specific assay conditions such as incubation time and temperature, quantity and avidity of the binding material, and specific activity and choice of the label. To compensate for variations in uptake values, the percent uptake for each unknown should be determined by comparison with a calibrator, reference material, or euthyroid reference serum of known percent uptake. Almost all commercial assays determine the percent uptake

directly from the radioactivity (in cpm) taken up on the secondary binder:

$$\%\ \text{uptake} = \frac{\text{cpm (patient)}}{\text{cpm (calibrator)}} \times \%\ \text{uptake (calibrator)}$$

Nonisotopic Methods

T_4 and T_3 uptake assays that use nonisotopic tracers have been developed and are available on most automated immunoassay instruments. Some methods use enzymes to label T_4 or T_3; different photometric, fluorescent, and luminescent substrates are available for monitoring the enzyme activity. Direct labeling of T_4 or T_3 antigens with fluorophores or chemiluminescence molecules is the most popular. These nonisotopic methods are generically named "uptake" assays, regardless of whether T_4 or T_3 is used as the labeled analogue. The competitive binder commonly used in many of these assays is a T_4 antibody bound to a solid phase. Some methods probe the total binding capacity of all thyroid hormone–binding proteins, but most estimate the concentration of unoccupied TBG binding sites. As mentioned, these T-uptake assays have essentially been replaced by the use of free hormone estimate assays to compensate for the variations in protein binding that affect total hormone assays.[57]

Some enzyme immunoassays for uptake do not require separation of the reactants. In the homogenous EMIT assay, a serum sample is incubated with a known amount of exogenous T_4, which binds to available sites on TBPs:

$$T_4\ (\text{exogenous}) + \text{TBP} \rightleftharpoons \text{TBP:}T_4 + T_4\ (\text{residual})$$

Residual T_4 is the the amount of T_4 that remains unbound and competes with the T_4 linked to glucose-6-phosphate dehydrogenase (T_4-E) for anti-T_4 antibody binding sites:

$$T_4 + T_4\text{-E (active)} + \text{Ab} \rightleftharpoons \text{Ab:}T_4 + \text{Ab:}T_4\text{-E (inactive)}$$

Binding of antibody to T_4-E decreases enzyme activity. The unbound T_4-enzyme conjugate, on the other hand, is active and catalyzes the oxidation of glucose-6-phosphate with simultaneous reduction of NAD+ to NADH. The rate of increase of absorbance at 340 nm is inversely proportional to the number of unsaturated TBP binding sites. Test results are expressed as percent of T uptake using a calibration curve or a mathematical function. Manual and automated versions of this assay are commercially available.[161,184]

Another homogenous immunoassay for T_4 uptake, based on CEDIA technology, uses the two inactive fragments EA and ED of β-galactosidase. In this assay, serum TBPs compete with EA for binding to an ED-T_4 conjugate. As the concentration of unsaturated TBPs increases, less ED-T_4 reassociates with EA to form the active enzyme:

$$\text{TBP} + \text{EA} + \text{ED-}T_4 \rightleftharpoons \text{ED-}T_4\text{:TBP} + \text{EA:ED-}T_4$$

The catalytic activity of the holoenzyme is inversely proportional to the concentration of unoccupied TBP binding sites and directly related to the percent T uptake. This assay has also been adapted for use on automated instruments.[85,103]

Several heterogenous enzyme immunoassays are commercially available for THBR assessment. In one competitive assay, a fixed excess of unlabeled T_4 is added to the serum specimen and binds to vacant sites on TBPs. The remaining unbound T_4 competes with an alkaline phosphatase–T_4 reagent for a limited number of binding sites on anti-T_4 polyclonal antibody immobilized on magnetic beads. As the concentration of unoccupied TBPs increases in serum, less unlabeled T_4 is available to compete with enzyme-labeled T_4 for antibody binding sites, and vice versa. Steric and molecular changes prevent enzyme-labeled T_4 from combining with endogenous serum proteins, and only unlabeled T_4 binds to TBPs. After washing to remove unbound components, the magnetic beads are incubated with a fluorogenic substrate. The enzyme activity measured in this assay (i.e., the fluorescence that is produced) changes in a direction opposite to the amount of radioactivity measured in the classic T_3-uptake test and is therefore directly proportional to the concentration of unoccupied TBP binding sites in the patient's serum but inversely related to the percent uptake.

Fluorescent and luminescence molecules have replaced radiolabels in the T-uptake test,[143] and both heterogenous and homogenous methods have been described. An example of the latter is the popular fluorescence polarization immunoassay for T uptake.[180] In this competitive assay, fluorescein-labeled T_4 is added to the serum specimen and binds to TBG and TBPA. As the number of T_4-binding sites increases, more labeled T_4 is bound. As a result, the degree of polarization of the protein-bound tracer increases, because this complex is larger than the free tracer. Specified quantities of T_4 antibody in a buffered protein matrix are used as calibrators. The observed polarization is directly proportional to the total serum TBP binding capacity and inversely related to percent T uptake. Test results are usually reported in "T-uptake units," but may be mathematically transformed into percent T-uptake equivalents. This method reflects the total number of binding sites rather than the concentration of unoccupied binding sites.[205]

To improve the understanding of THBR tests from different laboratories, the Committee on Nomenclature of the American Thyroid Association has recommended that uptake results for individual patients be normalized to those of a control serum (or reference serum pool) obtained from euthyroid patients who have normal quantities of TBPs.[114] The quotient of these results is proportional to the free fraction of T_4 or T_3 in serum and is properly known as the THBR:

$$\text{THBR} = \frac{\%\ \text{uptake (patient serum)}}{\%\ \text{uptake (reference serum)}}$$

A value of 1.0 indicates that the two values are identical. Some laboratories prepare their own normal reference serum pool, stored frozen at −70 °C in small aliquots, to analyze in every assay run. This enables the laboratory to maintain consistency in T-uptake values in case of changes in assay procedure or kit components. Other laboratories

determine a mean uptake value for their own local reference populations to use in calculating the THBR. Terms such as "T_3-resin uptake" or "T_3 uptake" are a continuing source of confusion and should be avoided.

Unfortunately, different laboratories calculate THBR either as being directly or indirectly related to TBG concentration and this causes laboratories and physicians confusion.

Specimen Collection and Storage. The preferred specimen is serum. Specimens may be stored at 4 °C for 1 week or at −20 °C for 30 days. Repeated freezing and thawing, mixing using a vortex mixer, or vigorous agitation of serum specimens should be avoided, because such treatment causes denaturation of proteins. The use of hemolyzed or lipemic specimens is also not recommended.

Reference Intervals. Although centered on a ratio of 1.0, reference values for THBR may differ by method and by local population. Each laboratory therefore should establish its own reference intervals. The following values are representative:[209]

	THBR
Cord	0.75-1.05
Children	
1-3 days	0.90-1.40
1-2 wk	0.85-1.15
1-4 mo	0.75-1.05
1-15 yr	0.88-1.12
Adult	0.83-1.15
>50 yr	
Male	0.87-1.11
Female	0.80-1.04
Pregnancy (last 5 mo)	0.68-0.87

Comments. In hyperthyroidism, more binding sites—and in hypothyroidism, fewer binding sites—on TBG are occupied by T_4. As a result, the THBR is high in hyperthyroidism and low in hypothyroidism. In cases of decreased and increased TBG (see Box 52-1), the THBR is high and low, respectively. Deviations of THBR and total T_4 in the same direction from normal (i.e., a concordant variance) suggest an abnormality in thyroid hormone production; a discordant variance suggests a primary change in the concentration or affinity of circulating TBG (Table 52-3).

TABLE 52-3 Diagnostic Utility of THBR and FT_4 Index

Clinical Condition	Total T_4	THBR	FY_4I
Euthyroid	N	N	N
Hyperthyroid	↑	↑	↑
Hypothyroid	↓	↓	↓
Increased TBH	↑	↓	N
Decreased TBH	↓	↑	N

N, Normal; ↑, increase; ↓, decrease.

Calculation of Free T_4 and T_3 Indexes

The THBR assay is not designed to be used as an independent and isolated test for thyroid disease. It is useful only when combined with a measurement of total T_4 (or T_3) concentration to calculate an FT_4 or FT_3 index.

Principle

The calculation of an FT_4 index is based on the equilibrium relationship that exists between bound [TBP:T_4] and FT_4:

$$[FT_4] + [uTBP] \underset{}{\overset{K}{\rightleftharpoons}} [TBP{:}T_4]$$

Here, [uTBP] represents unsaturated (unoccupied) binding sites on TBPs, and K represents the equilibrium constant for the interaction. This interaction can also be expressed by the mass action equation:

$$K = \frac{[TBP{:}T_4]}{[FT_4] \times [uTBP]}$$

Rearranging,

$$K[FT_4] = \frac{[TBP{:}T_4]}{K[uTBP]}$$

Because more than 99.97% of the total T_4 circulating in blood is protein bound, the term [TBP:T_4] is essentially replaced by the total T_4 concentration. Also, because [uTBP] (the concentration of unoccupied TBP binding sites) varies inversely with the THBR, then

$$K \times [FT_4] = [T_4] \times \frac{1}{[uTBP]} = [T_4] \times THBR$$

If FT_4I is defined as $K \times [FT_4]$, then

$$FT_4I = [T_4] \times THBR$$

The FT_3 index is calculated similar to the FT_4 index, as $T_3 \times$ THBR, and is used in the same way as an estimate of FT_3. In general, the FT_3 index offers no advantage over the FT_4 index and is used less frequently in clinical practice.

Reference Intervals

Reference intervals for FT_4 and FT_3 indices are derived in two ways: (1) directly from matched total T_4 (or T_3) and THBR results obtained from a sufficiently large number of euthyroid individuals or (2) indirectly by calculation from reference intervals established for total T_4 (or T_3) and THBR. In the latter case, the lower limit of the FT_4 index is calculated by multiplying the lower limit of the THBR interval and the lower limit of the T_4 interval; the upper limit of the FT_4 index interval is obtained by multiplying the upper limit of the THBR interval and the upper limit of the T_4 interval. Estimates based on calculation may yield a broader reference interval for FT_4 and FT_3 indices than the first approach.

Reference intervals are numerically close to the normal intervals for total T_4 or T_3. Most automated immunoassay analyzers are capable of performing the THBR and total T_4 tests with online calculation of the FT_4 index. Theoretically, because the calculated indices are products of T_4 or T_3 concentrations and a ratio, they have concentration units. However, to avoid confusion with serum T_4 or T_3, the free hormone index units are usually omitted or termed "index units." Typical values are as follows:[52]

	FT_4 Index	
	µg/dL	nmol/L
Cord	6.0-13.2	77-170
Infant		
1-3 days	9.9-17.5	128-226
1 wk	7.5-15.1	97-195
1-12 mo	5.0-13.0	65-168
Children		
1-10 yr	5.4-12.8	70-165
Pubertal child and adult	4.2-13.0	54-168

Comments

A number of pseudonyms for the FT_4 index have appeared in the literature and in commercial kits; this has led to some confusion. Effective thyroxine ratio, T-7, and T-12 are only a few examples. Such terms are now archaic and should not be used.

Unlike direct FT_4 methods, index methods measure both the serum total T_4 and the FT_4 fraction and have the advantage that they can define whether an abnormal FT_4 estimate is due to abnormal hormone production or to abnormal protein binding.

An FT_4 index is sometimes directly calculated using the percentage T uptake:

$$FT_4I = \text{Total } T_4\ (\mu g/dL) \times \frac{\%\ T\ \text{uptake}}{100}$$

FT_4I = Total T_4 (mg/dL) × % T uptake/100

Typical reference intervals are 1.5 to 4.4. Calculations using THBR are preferred.[114]

Calculation of T_4/TBG and T_3/TBG Ratios

Measurements of serum TBG concentration have been used in the diagnosis of thyroid disease in two ways. The most common approach is to calculate a T_4:TBG or T_3:TBG ratio.[18] Such indices are derived from mass action equations and are used to approximate FT_4 or FT_3 concentrations. These ratios correlate variably with FT_4 or FT_3 concentrations and are particularly useful in sera with altered TBG concentrations; however, they may fail to compensate for TBG variants with reduced T_4 affinity or for abnormal albumin binding. The reference interval for T_4:TBG ratios is 3.8 to 4.5 when the reference intervals for total T_4 and TBG are 4.5 to 12.5 µg/dL and 1.2 to 2.8 mg/dL, respectively.

Measurements of TBG also have been used to derive values for FT_4 or FT_3 by calculation. Assuming TBG is the major determinant of thyroid hormone binding, serum concentrations of TBG and total T_4 (or T_3), together with the association constant for the binding of T_4 (or T_3) to TBG, are used to calculate values of the free hormone. In most cases, these calculated values correlate well with those directly determined.

Direct Immunoassay Methods

Immunoassays of various designs for estimating free thyroid hormones using antibody extraction techniques have been developed.[48,122] These assays are subdivided as either *sequential two-step assays* or *simultaneous one-step ("analogue") assays.* Each procedure involves the direct incubation of serum with a specific anti-T_4 or anti-T_3 antibody, during which thyroid hormones reach a new equilibrium with all of the binders present. A slight decrease in free hormone concentration occurs, but is insignificant if the antibody sequesters less than 5% of the total amount of hormone present in the specimen. Thus the amount of immunoextracted T_4 or T_3 closely approximates the undisturbed free hormone concentration that preexists in serum at equilibrium.

Two-Step Immunoassays. These methods use two processing steps. In the first step, the serum specimen is incubated briefly with specific solid-phase antibody. Under standard conditions of temperature and incubation time, a percentage of the total thyroid hormone proportional to the original FT_4 or FT_3 concentration is extracted and bound by the antibody. After thorough washing to remove serum proteins and other interfering substances, a second step estimates the remaining unoccupied (vacant) antibody binding sites by back titration with labeled T_4 or T_3. Excess label is then washed away from the solid-phase antibody, and the quantity of bound tracer is compared with a calibration curve generated from secondary calibrators that have had target values assigned to them by a reference method. The amount of labeled hormone retained by the antibody is inversely related to the free hormone concentration in the test specimen.

The key feature of this two-step method is that the labeled hormone is physically prevented from interacting with serum binding proteins. This ensures that antibody binding of tracer is governed solely by the free hormone concentration and not by changes in thyroid hormone–binding proteins. Test results obtained with two-step methods correlate well with those obtained by reference methods across a wide range of clinical disorders.

A sequential two-step immunoassay for FT_4 was first introduced commercially in 1979.[34] Subsequently, a number of manual and automated procedures have become available for FT_4 and FT_3. The earliest kit methods used radioactive labels and antibody-coated tubes or microbeads, but automated systems are now available that use nonisotopic tracers and a variety of solid-phase formats.[20] One two-step FT_4 method involves the application of serum to glass-fiber

paper on which the clinical specimen reacts with preimmobilized anti-T_4 antibody.[187] After a 2-minute incubation period, an alkaline phosphatase–labeled T_4 conjugate binds to unoccupied antibody binding sites and at the same time washes out the protein-bound T_4 fraction. After a second incubation (3 minutes), excess unbound conjugate is washed from the filter paper by radial elution. A fluorogenic substrate for the enzyme is also included in the wash solution to initiate the enzyme reaction. Enzyme activity of the bound conjugate is measured by front-faced fluorimetry and is inversely related to the concentration of FT_4 in the sample.

Two-step microparticle capture immunoassays have been developed to fully automate the measurement of free thyroid hormones.[12,89] In one type of FT_4 assay, FT_4 is first immunoextracted from serum using polyclonal anti–T_4-coated latex microparticles; T_4 bound to serum proteins does not react with the antibody. An aliquot of the reaction mixture is then transferred to a glass fiber matrix that irreversibly captures the T_4–anti-T_4–microparticle complex; washing removes any serum materials not bound to the solid phase. In the second back-titration step, the remaining unoccupied antibody binding sites are reacted with a T_3–alkaline phosphatase conjugate; serum binding proteins are not available for binding to this enzyme conjugate. Excess unbound enzyme conjugate is removed by washing followed by addition of the substrate, 4-methylumbelliferyl phosphate, to the matrix cell. The concentration of the fluorescent product varies inversely with the amount of FT_4 in the serum. A T_3–alkaline phosphatase conjugate is used in this assay system rather than a T_4 conjugate because of its lower affinity for the anti-T_4 antibody. Although the T_3 conjugate possesses the ability to bind to vacant anti-T_4 sites on the microparticles, this enzyme label does not displace or dislodge FT_4 already bound to the microparticles. The detection limit of this assay (defined as mean minus 2 SD of the zero calibrator) is approximately 0.4 ng/dL. Interassay reproducibility, expressed as coefficient of variation, is typically ±3% to 6% over a concentration range of 0.6 to 3.5 ng/dL (8 to 45 pmol/L); cross-reactivity with FT_3 is less than 0.5%.

One-Step Immunoassays. These methods are widely used for direct estimation of FT_4 or FT_3 and are known as one-step or "hormone analogue" immunoassays. These single-step techniques are usually subdivided into formats relying on labeled hormone analogue and solid-phase antibody or those relying on labeled antibody and solid-phase hormone analogue. Both approaches use structurally modified analogues of thyroid hormones that, in theory, retain the ability to compete with free hormone for binding to specific anti-T_4 or anti-T_3 antibodies but are chemically restricted from interacting with thyroid hormone–binding proteins in the serum specimen. Unlike two-step methods, analogue assays rely on simultaneous rather than sequential back-titration of unoccupied antibody-binding sites. For one-step methods to succeed, the hormone analogue should not displace T_4 (or T_3) from binding proteins; binding of the hormone analogue by serum proteins must be either totally absent or essentially insignificant.

Labeled-Analogue Methods. In a typical one-step RIA for FT_4, endogenous free hormone and a ^{125}I-labeled T_4 analogue compete for solid-phase antibody binding sites in the presence of serum protein; the amount of labeled analogue bound by the specific antibody is inversely related to the amount of FT_4 in the specimen.[106] Test results are expressed relative to secondary serum calibrators that have been independently calibrated using equilibrium dialysis or ultrafiltration techniques. A number of one-step RIAs have been developed and are commercially available.

The chemical composition of the labeled hormone analogues used in commercial kits is proprietary. However, it has been speculated that some analogue tracers are produced by altering the alanine side chain of the iodothyronine molecule, thus hindering the binding of TBG and TBPA. Unfortunately, most of these synthetic analogue tracers bind significantly to serum proteins, particularly albumin, resulting in inaccurate free hormone measurements when the albumin in patient specimens differs from that in the assay calibrators. Attempts have been made to limit albumin binding by using chemical blockers to saturate albumin binding sites. However, some of these blockers also displace T_4 from TBG, thereby disrupting the equilibrium between free and protein-bound hormone during the assay and making these modified assays TBG-dependent.

It is known that the presence in serum of an abnormal amount of any substance affecting analogue binding—such as endogenous antibody, nonesterified fatty acids, or certain anions—greatly distorts assay results.[50,51] If analogue binding to protein is greater in the serum sample than in the calibrators, as in dysalbuminemia or with T_4 autoantibodies, then less analogue tracer is available to compete for the assay antibody, thus giving a falsely high FT_4 estimate. Conversely, if analogue binding to protein is less in the sample than in the calibrators, e.g., increased binding of albumin by nonesterified fatty acids or decreased serum albumin concentration, then FT_4 estimates are falsely low.[200]

Techniques involving nonradioactive conjugates that claim to reduce some of these problems have been introduced. For example, one-step enzyme immunoassays for FT_4 in which a T_4-peroxidase conjugate competes with FT_4 for a solid-phase antibody have been described.[108] A chemiluminescence system based on similar principles involves the use of a T_4-acridinium ester conjugate that competes with free hormone for binding sites on antibodies immobilized on paramagnetic particles.[110] Manufacturers claim that these conjugates are insignificantly bound by serum-binding proteins. A number of automated immunoassay systems based on single-step, labeled-analogue methods are commercially available for estimating both FT_4 and FT_3 concentrations.

Labeled-Antibody Method. Most one-step immunoassays use labeled analogues of T_4 or T_3. Alternatively a number of labeled antibody methods have also been developed in which the distribution of a labeled antibody between exogenous

TABLE 52-4 Free Thyroxine Measurements in Common Conditions Affecting Thyroid-Binding Proteins

solid-phase hormone and free hormone reflects the free hormone concentration.[26,27,181] This assay design is similar to the labeled-analogue principle except that unoccupied antibody-binding sites are identified by their absorption from the reaction mixture onto a hormone analogue coupled to a solid support. Linking of T_4 or T_3 to the solid phase creates a macroanalogue with a reduced interaction with serum proteins.[49,159] These labeled-antibody assays are claimed to be more reliable than labeled-analogue methods and to be less sensitive to major protein modifications or progressive dilution of serum.

Reference Intervals.[33] Expected values using a one-step immunochemiluminometric assay are as follows: for FT_4, 0.8 to 2.3 ng/dL (10 to 30 pmol/L); for FT_3, 230 to 420 pg/dL (3.5 to 6.5 pmol/L).

Selection and Use of Tests for Measuring Free Thyroid Hormones

Estimates of FT_4 and FT_3 generally give results in healthy subjects, hyperthyroid and hypothyroid patients, and patients with only mild binding protein abnormalities that are comparable with those of reference methods such as direct equilibrium dialysis and RIA assays. In these individuals, the selection of a specific FT_4 or FT_3 measurement method can be based on factors such as technical convenience, turnaround time, commercial availability, and cost. In certain clinical conditions, free hormone estimate methods may give abnormal results that differ from the generally normal values obtained using direct reference methods. These abnormalities, summarized in Table 52-4 and discussed later, are commonly encountered in euthyroid patients who show significant changes in T_4 or T_3 binding to serum proteins. In these situations, the selection of appropriate FT_4 or FT_3 estimate methods should be based more on their analytical and diagnostic reliability than on the ease of performance and cost.

Unfortunately, FT_4 and FT_3 estimate methods have been found to be unreliable in a number of situations. One of these is familial dysalbuminemic hyperthyroidism, an inherited disorder in which a normally minor component of serum albumin is increased. This variant albumin binds T_4 with abnormally high affinity, but its avidity for T_3 is not comparably increased. Although total T_4 concentrations are usually high, patients with familial dysalbuminemic hyperthyroidism are clinically euthyroid, and free hormone concentrations are normal as measured by reference methods

and by most two-step immunoassays. However, if tracer T_3 is used to estimate the FT_4 fraction, the resin uptake and THBR results are normal, and the calculated FT_4 index is falsely increased. (In contrast, uptake methods using T_4 tracers provide more accurate THBR and FT_4 index values.) One-step immunoassays likewise give high FT_4 estimates owing to the binding of the T_4 analogue to the variant albumin. Test results similar to those in familial dysalbuminemic hyperthyroidism are also obtained from patients with circulating T_4 autoantibodies or when T_4 binding by prealbumin is increased.

In addition, FT_4 and FT_3 estimate methods are not reliable when used in patients with congenital TBG excess or deficiency. Patients with these conditions are clinically euthyroid, and their FT_4 and FT_3 concentrations are normal as determined by direct reference methods and two-step immunoassays. Index methods and one-step analogue immunoassays, however, yield abnormal results. For example, in the case of TBG excess, total serum concentrations of T_4 and T_3 are increased, and the THBR is low. However, the THBR is not linearly related to the free fraction of T_4 or T_3 at extremes of the free fraction range. Accordingly, the THBR cannot be reduced as much as the free fraction, and the calculated FT_4 index is abnormally high.

Another situation in which free hormone estimates may be unreliable is in the assessment of critically ill patients who are believed to be euthyroid (i.e., have a nonthyroidal illness). For example, serum FT_4 concentrations in nonthyroidal illness patients with low total T_4 values are usually normal or high by reference methods, whereas most FT_4 or FT_3 estimates give low values, although some consistently provide normal results. Distinguishing severe nonthyroidal illness from true hypothyroidism presents a difficult analytical challenge. This is why the current NACB guidelines recommend the use of TT_4 in preference to current FT_4E tests.

Estimates of FT_4 or FT_3 may be profoundly affected by medications that compete with T_4 or T_3 for binding to serum proteins. With reference methods that use undiluted serum, the free hormone concentration may rise and eventually return to a new steady state in the presence of T_4- or T_3-displacing drugs. In contrast, most estimates of FT_4 or FT_3 use diluted serum in which the drug competitor declines before the free hormone declines. Consequently the hormone-displacing effect of the drug also decreases, leading to a major underestimation of the true FT_4 concentration.

Rigorous evaluation of free thyroid hormone methods is required before new assays are placed into clinical service.[80] Performance data on analytical accuracy should be obtained not only on serum from patients with thyroid dysfunction but also in serum from patients with binding protein abnormalities. Effects of drugs that compete for hormone binding sites on serum proteins should also be evaluated. Moreover, adequate assessment requires an examination of the effects of progressive sample dilution. In theory, the free concentration of T_4 and T_3 should not decrease with dilution until about 20% of the bound ligand is dissociated. In the case of T_4, this decrease occurs at a dilution of about 1:1000 (1:100 for T_3). Near constancy of assay results in the face of progressive serum dilution is widely accepted as the classic test of FT_4 (or FT_3) validity.[47,148,225] In practice, many methods demonstrate lower than predicted free hormone concentrations with dilution.

Determination of Thyroxine-Binding Globulin and Other Thyroid Hormone–Binding Proteins

TBG is the thyroid hormone–binding protein having the greatest affinity for T_4. As such, it is very important in regulating the concentration of the FT_4 hormone. Estrogen-induced TBG excess and congenital TBG deficiency are the most significant TBG abnormalities that affect the interpretation of thyroid function test results (see Box 52-1).

Principle

TBG is measured indirectly in terms of its T_4-binding capacity or preferably by the direct determination of the protein concentration of TBG. Tests based on binding capacity are usually performed by adding to the test serum a mixture of unlabeled and radiolabeled T_4 in a concentration sufficient to saturate all the binding sites on the TBG. Binding to T_4-binding prealbumin (transthyretin, TBPA) can be blocked by carrying out the reaction in a barbital buffer; the excess (unbound) T_4 is removed with dextran-coated charcoal that also strips T_4 from albumin and other weak binders. The fraction of radioactivity associated with the supernatant is then multiplied by the amount of T_4 added to the serum to give the T_4-binding capacity for TBG (units: μg T_4/dL). In normal adult sera, the binding capacity for TBG ranges from 16 to 24 μg T_4/dL. Although this assay is relatively specific for TBG (i.e., TBPA and albumin do not react appreciably), various drugs or abnormal thyroid hormone binders may interfere by inhibiting T_4 binding, thus giving artificially low values for TBG.

Direct measurement of the protein concentration of TBG by immunoassay is more widely used because it is technically less complex and offers increased precision and immunospecificity. A typical RIA measures the competition between endogenous TBG and ^{125}I-labeled TBG for binding with a limited quantity of TBG antisera.[69] After incubation, bound and free fractions are separated using either a polyethylene glycol precipitant or a mixture of polyethylene glycol and second antibody. Commercial kits based on both isotopic and nonisotopic formats are available. One competitive chemiluminescence enzyme immunoassay for TBG makes use of peroxidase-labeled TBG and TBG antibody, which is captured by a solid-phase second antibody.[133] The bound conjugate is measured by enhanced luminescence after the addition of luminol and hydrogen peroxide. The dynamic range of the assay is 5 to 80 mg/L, and the interassay imprecision is less than ±10% at three concentrations. In healthy adults, the reference interval is 12 to 28 mg/L. Automated nonisotopic immunoassays for TBG are also available, such as the procedure based on the principle of

enhanced microparticle turbidimetry.[73] In this test, the rate of agglutination of serum TBG and a solid-phase TBG antibody is determined by measuring the absorbance change at 600 nm.

TBG tests that use labeled T_4 have also been developed. In one commercial assay, a two-site IRMA or "sandwich" assay is used.[207] TBG antibody bound to glass particles is added in excess to the patient specimen and binds virtually all the endogenous TBG present. ^{125}I-T_4 is then added; it binds to the TBG, forming an anti-TBG-TBG-^{125}I-T_4 sandwich. After a short 15-minute incubation period at room temperature, the precipitate is collected by centrifugation and its radioactivity is counted. Test values are interpreted from a calibration curve run simultaneously with the patient specimens. Unlike the typical RIA procedure, radioactivity in this IRMA method is directly proportional to the amount of TBG present in the specimen. Patients with molecular variants of TBG may have discordant results, but the assay is not affected by excess thyroxine or phenytoin.[147]

Individual TBPs have been measured using electrophoresis to assess binding of radioactive T_4.[101] In this procedure, excess unlabeled T_4 and radiolabeled T_4 are added to the test specimen to saturate the binding of TBG. Total T_4 is determined on this enriched serum, which is then subjected to electrophoresis. Radioactivity bound to the individual protein bands (albumin, prealbumin, and TBG) is counted, and the fraction associated with each band is calculated. The fractional radioactivity is then multiplied by the total T_4 concentration in the T_4-enriched serum to give the T_4-binding capacity of each particular protein. Binding capacity of TBG for T_4 in normal serum generally ranges from 10 to 25 μg/dL of prealbumin for T_4 from 49 to 70 μg/dL, and of albumin for T_4 from 12 to 34 μg/dL.

The major application of this electrophoretic method is the identification of patients with euthyroid hyperthyroxinemias or euthyroid hypothyroxinemias.[81] This assay distinguishes abnormalities in the concentration of normal T_4-binding proteins from abnormal binding proteins with altered affinities for T_4. Congenital and drug-induced elevations (or deficiencies) of TBG are examples of the former. Anti-T_4 antibodies and unusual forms of albumin and prealbumin are examples of the latter.

Specimen Collection and Storage

Serum is the preferred specimen; plasma with EDTA or heparin as anticoagulant may also be used. Serum specimens are best stored at 2 °C to 8 °C if they will not be tested within 24 hours. If longer periods of storage are necessary, freezing the specimens is recommended. Frozen specimens are stable for at least 30 days. Repeated freezing and thawing of the specimens should be avoided. Turbid samples should be centrifuged before testing.

Determination of Thyroglobulin

Tg is a large glycoprotein having a molecular weight of 660 kDa that is stored in the follicular colloid of the thyroid gland. It functions as a propeptide for the intrathyroidal synthesis of T_4 and T_3. It is made by the follicular cells and secreted into the follicular lumen where it is iodinated, after which its iodinated tyrosyl moieties form T_4 and T_3. Thyroglobulins are then taken up by endocytosis into the follicular cells, where T_4 and T_3 are liberated by proteolysis, followed by release into the extracellular fluid and thence to the bloodstream.

Principle

Traditionally, circulating concentrations of Tg have been measured using double-antibody immunoassays.[213] Commercial RIA kits based on sequential addition techniques have been developed for routine use. These methods involve the preliminary incubation of serum with primary antibody. After a number of hours (2 to 72), the Tg tracer is added and allowed to compete for antibody binding sites. The longer the preincubation the more sensitive the method. Separation of bound from free Tg is then accomplished by precipitation with a second antibody.

Two-site immunometric assays have also been developed for Tg. These assays are based on the use of two or more monoclonal antibodies directed to different portions of the Tg molecule. One of the antibodies is attached to a signal molecule, such as a radioisotope, enzyme, or chemiluminescent molecule, and the other to a solid support, such as polystyrene beads or magnetic microbeads.[160,175,226] Another variation is to attach biotin to the antibody and separate the Tg complex using avidin linked to a solid phase.[86,93] Commercial kits based on these techniques are available. Compared to RIAs, these immunometric assays have the advantage of shorter incubation times, a larger working range, a more stable labeled antibody reagent, longer shelf life, and potential for automation. Interassay reproducibility, expressed as a coefficient of variation, is typically less than ±6% at the optimal dose range but can rise to >15% at the extremes of the curve. Limit of detection, derived from the 20% coefficient of variation point of the interassay precision profile, is 0.5 to 1.0 ng/mL.[93] Most current immunometric assays are calibrated using a Tg reference preparation developed by the Community Bureau of Reference. Use of this standard reduces interassay variability somewhat to around 30%, a value that is threefold higher than the within-person variability.[197] The high between-method variability precludes switching between methods during long-term monitoring of patients.

A major difficulty in most immunoassays for Tg is interference due to endogenous anti-Tg antibodies that are present in about 15% to 35% of thyroid cancer patients. Interference effects can be substantial, causing either an overestimation or an underestimation of the true value. With newer immunometric assays, this effect is an underestimation. It is crucial that all serum samples be screened for the presence of anti-Tg with a sensitive immunoassay.[125] When detected, the concentration of such antibodies should be reported, and a warning issued to clinicians to interpret the

serum Tg value with caution. Some laboratories assess the impact of anti-Tg interference by measuring the recovery of known amounts of Tg added to patient sera.[55,172,208] If Tg recovery is high (90% to 110%), then significant autoantibody interference may be absent. The reliability of recovery studies, however, has been disputed and is currently discouraged by the NACB.[197] A multisite immunoradiometric assay (IRMA) also has been reported to measure serum Tg with minimal interference from anti-Tg autoantibodies (TgAb).[127] This assay uses five different monoclonal antibodies directed against antigenic regions on the Tg molecule that are not recognized by most anti-TgAb. Four of these antibodies are coupled to polystyrene tubes, and the fifth is coupled to radioiodine. Unfortunately, this approach has not been found to overcome TgAb interference.

Other technical problems, such as heterophilic antibody (HAMA) interference, may limit the clinical value of Tg measurements. Recommendations regarding approaches to standardization, precision, limits of detection, and hook effects have been suggested.[196] Serum Tg values obtained by different methods are usually not interchangeable, and the same assay should be used to perform serial serum Tg measurements in a patient. When a change in method is made, the laboratory should define performance characteristics of the new method and validate its clinical utility before implementing the method for patient care.

Specimen Collection and Storage

Serum is the preferred specimen; plasma with EDTA or heparin as anticoagulant may also be used. Serum specimens are best stored at 2 °C to 8 °C if they will not be tested within 24 hours. If longer periods of storage are necessary, freezing the specimens is recommended. Frozen specimens are stable for at least 30 days. Repeated freezing and thawing of the specimens should be avoided. Turbid samples should be centrifuged before testing.

Reference Interval

The reference interval for Tg in euthyroid individuals ranges from a lower limit of 0.5 to 3 to an upper limit of 20 to 42 ng/mL (3 to 42 μg/L), depending on the method.[131,209] For athyreotic patients not receiving T_4, replacement therapy should have undetectable serum Tg irrespective of TSH status. Tg concentrations are elevated in the neonate and decrease significantly during the first 2 years of life.

Comments

Tg is primarily used as a tumor marker in patients carrying a diagnosis of differentiated thyroid carcinoma (DTC). Although serum Tg is elevated in patients with thyroid cancer, including thyroid follicular and papillary carcinoma, elevations are also are seen in nonneoplastic conditions such as thyroid adenoma, subacute thyroiditis, Hashimoto's thyroiditis, and Graves' disease. Serum Tg concentrations are not increased in patients with medullary thyroid carcinoma. Serial measurement of Tg is most useful in detecting recurrence of DTC following surgical resection or radioactive iodine ablation.[111] Tg determination is used as an adjunct to ultrasound and ^{134}I scanning. Assessment of serum Tg also aids in the management of infants with congenital hypothyroidism. All patients with hyperthyroidism should have elevated Tg; low concentrations of Tg may be an indication that thyrotoxicosis factitia is present.

Determination of Antithyroid Antibodies

Increased circulating concentrations of antithyroid antibodies are found in a variety of thyroid disorders and in other autoimmune diseases and certain malignancies. These autoantibodies are directed against several thyroid and thyroid hormone antigens, including Tg (TgAb), thyroid peroxidase (TPOAb), thyroidal microsomal antigen, the TSH receptor (TRAb), a non-Tg colloid antigen, TSH, T_4, and T_3. Of these antibodies, TPOAb is most commonly used in evaluating thyroid autoimmune diseases, whereas TgAb is used for detecting interference with Tg measurement.

Antithyroglobulin Antibodies

Tg antibodies are directed against the Tg protein, a major constituent of thyroid colloid. Several different techniques have been used to detect and quantify TgAb in peripheral blood. These include passive hemagglutination, the agar gel diffusion precipitin technique, immunofluorescence of tissue sections, enzyme-linked immunosorbent assay (ELISA), radioassay techniques, and chemiluminescence-based immunometric assays.

Principle

In the tanned erythrocyte hemagglutination method, an aliquot of patient serum is mixed with erythrocytes that have been treated with tannic acid and then coated with purified human Tg. When antibodies in the patient's serum combine with Tg antigen bound to erythrocytes, agglutination of the erythrocytes occurs. The use of Tg-coated erythrocytes makes this agglutination reaction much more sensitive than a simple antigen-antibody reaction. Several commercial kits are available for measuring anti-Tg antibodies in serum. A commonly used one is based on the passive hemagglutination method of Boyden.[11] In this system, turkey red blood cells coated with Tg are agglutinated by the specific antibody, yielding a smooth carpet of cells at the bottom of a microtiter well. Lack of agglutination is indicated by the settling of the cells into a compact ring or button. Before testing, patient sera are deactivated at 56 °C for 30 minutes. Heating is important for inactivation of complement and TBG, which otherwise would interfere with the assay.

Serial dilutions of the patient's serum are used to establish a Tg antibody titer. The reported result is the highest dilution that causes agglutination. Titers are usually considered negative at a less than 1:10 dilution ratio. This hemagglutination test is not highly specific, and about 5% to 10%

of the normal population may have a low titer of Tg antibodies with no symptoms of disease, an incidence that is higher in women and that increases with age. Reactivity occurs more frequently in Hashimoto's thyroiditis (>85% of patients) and Graves' disease (>30% of patients); titers greater than 1:1600 are common. Positive responses are also seen in patients with idiopathic myxedema (>75% of cases), but antibody titers are generally lower. Weakly positive tests may also be found in patients with nontoxic goiter, thyroid cancer, and pernicious anemia; in these patients, antibody titers are not found with any greater frequency than in an unselected population.

Agglutination tests are being rapidly replaced by more sensitive immunoassays that can be automated. Radioimmunoassays, ELISA, and chemiluminescence-based immunoassays have been all been developed for measuring both Tg and TPO antibodies.[144] Several commercial kits and automated methods are currently available, including systems based on Tg-coated cells, particles, magnetic beads, microtiter plates, or tubes and chemiluminescence automated instruments. These methods correlate well with agglutination tests and are generally more sensitive and more specific for thyroid autoimmune diseases. Some assays allow identification of subclasses of Tg antibodies; the clinical significance of these subclasses, however, is not known.

In a typical IRMA,[1] Tg antibodies in diluted serum specimens bind to human Tg in coated test tubes. After incubation for 1 hour at 37 °C, the tubes are washed and ^{125}I-labeled protein A is added. After another 1 hour of incubation at 37 °C, the supernatants are washed again and the radioactivity counted. The amount of bound radioactivity in each tube is directly proportional to the amount of anti-Tg antibody present. Interassay precision is about 3% at 36 U/mL.

A nonisotopic ELISA method in which serum specimens are added to microtiter wells coated with human Tg is also available.[176] In this method, antibody binding is assessed using a peroxidase-conjugated anti-IgG/*o*-phenylenediamine system. An automated two-step fluorescent enzyme immunoassay has been reported.[183] In this assay, Tg is immobilized on magnetic beads, and anti-human IgG mouse monoclonal antibody is labeled with alkaline phosphatase; 4-methylumbelliferyl phosphate is used as the substrate. IRMA and ELISA both have similar detection limits (approximately 3 to 5 U/mL). A considerably more sensitive radioassay has been reported in which diluted serum is incubated with ^{125}I-labeled Tg to allow formation of antigen-antibody complexes[9]; these complexes are then precipitated by adding solid-phase protein A. Its detection limit is reported to be approximately 0.2 U/mL.

Specimen Collection and Storage

The preferred specimen for testing is serum, which should be kept frozen if the test is not performed on the day that the blood is drawn. Repeated freezing and thawing must be avoided.

Reference Interval

Assessment of a normal reference interval for anti-Tg antibodies is controversial, mainly due to the fact that Tg autoantibodies have been found in individuals without apparent thyroid disease. Variable reference intervals have been reported, depending on whether a random population was sampled or a population without active or previous thyroid disease. Thyroglobulin antibodies follow a logarithmic normal distribution and are usually expressed as units per milliliter with reference to the MRC 1st IRP for Thyroglobulin Autoantibody 65/93. As with TPOAb, TgAb methods fall into two classes. Class 1 methods have a lower numeric detection limit (<2 IU/ml) and report that normal individuals should not have antibody detected. Class 2 methods have a higher numeric detection limit (>10 IU/mL) and report a "normal range.[33]"

Comments

The measurement of TgAb adds little diagnostic information over and above TPOAb measurement for diagnosing autoimmune thyroid disease.[85A] However, measurement of TgAb is needed to identify sera with autoantibodies that may interfere with serum Tg measurements in patients being managed for treatment of thyroid carcinoma.

Antimicrosomal/Antithyroid Peroxidase Antibodies

Principle

Antimicrosomal antibodies are directed against a protein component of thyroid cell microsomes. These autoantibodies are measured using complement fixation, immunofluorescence of tissue sections, passive hemagglutination, ELISA techniques, or radioassay methods. The tanned erythrocyte agglutination method uses cells that have been coated with microsomal antigen isolated from human hyperplastic thyroid glands. This semiquantitative procedure is simple, and commercial kits are available. Reactivity occurs in nearly all adult patients with Hashimoto's thyroiditis and in about 85% of patients with Graves' disease. Low titers, however, may be seen in 5% to 10% of normal asymptomatic individuals. Hemagglutination tests for TgAb and TPOAb are often performed together. Of the two, the result of the one for TPOAb is more frequently positive for thyroid autoimmune disease and usually is in higher concentration. This is particularly the case in patients younger than 20 years.

Procedures for the more sensitive ELISA and radioassays are similar to those previously described for anti-Tg antibodies; a number of quantitative commercial kits are available. A combined micro-ELISA for simultaneous measurement of TgAb and TPOAb antibodies in a single test has also been described.[151] Microsomal antibody concentrations are usually expressed in units per milliliter with reference to the MRC IRP for Microsomal Autoantibody 66/387. The mean TPOAb activity, measured with an IRMA kit, is 280 ± 60 IU/mL in normal sera.[129]

The enzyme TPO is now recognized as the principal and possibly only autoantigenic component of thyroid microsomes. Assays based on TPO itself are preferred for routine clinical use in the management of patients with suspected autoimmune disease of the thyroid. Performance of antimicrosomal antibody assays is complicated by the limited availability of human thyroid tissue, the presence of irrelevant thyroid antigens and autoantibodies, and the contamination of microsome preparations with Tg.[53] These complications seem to have been eliminated by using TPO as the antigen.

Purification of TPO by affinity chromatography or production by recombinant techniques has led to the development of assays for anti-TPO antibodies based on RIA or chemiluminescence-based immunometric techniques.[59,61] These procedures provide greater sensitivity and specificity than passive hemagglutination assays for microsomal antibodies in detecting, confirming, and monitoring autoimmune thyroid disorders[126,129] and are more suitable for screening or high-volume testing. The immunometric assay of Ruf and coworkers,[167] for example, is based on competitive inhibition of the binding of radioiodinated TPO to an anti-TPO monoclonal antibody coated onto plastic tubes. This assay is rapid (only one 2-hour incubation period is involved), easy to perform, and available as a commercial kit. The design of the assay ensures specific measurement with minimal interference from Tg or TgAb. Manual and automated nonisotopic immunoassays for anti-TPO are also available[81,86,183]; detection limits range from 0.3 to 2 U/mL.

Reference Interval

The normal reference interval for TPOAb is controversial. With sensitive assays, low concentrations of TPOAb may be detected in some healthy individuals without thyroid disease. There is a high prevalence of anti-TPO antibodies in the elderly.[203] However, longitudinal studies suggest that the presence of TPOAb is a risk factor for autoimmune thyroid dysfunction. TPO antibody concentrations are usually expressed as units per milliliter with reference to the MRC Standard 66/387. With a competitive IRMA, the mean TPOAb activity in normal sera is 69 ± 15 U/mL (SEM).[129] Using a sensitive chemiluminescence assay, values are less than 2 U/mL.[33]

Comments

Detectable concentrations of TPOAb are observed in nearly all patients with Hashimoto's thyroiditis and idiopathic myxedema and in the majority of patients with Graves' disease. These antibodies have also been demonstrated in the sera of patients with type I insulin-dependent diabetes mellitus. The frequency of detectable TPOAb antibodies observed in nonimmune thyroid disease is similar to that observed in a normal population.[53]

Thyrotropin-Receptor Antibodies
